## **ACKNOWLEDGMENTS**

All praise and thanks to Almighty Allah for giving me health, strength, patience and knowledge. I would like to express my great thanks to King Fahd University of Petroleum and Minerals (KFUPM), namely, the Chemical Engineering Department (CHE) for hosting me since 2009 when I started doing the bachelor degree. In particular, I am very thankful to all CHE faculties.

My special thanks to my advisor Dr. Zuhair Omer Malaibari for his support, guidance and valuable comments. Also my special thanks go to Dr. Oki Muraza for his always support, encouragement and guidance since I was doing the COOP program and up to today. I am very thankful to my committee member Dr. Adnan Al-Amer, Dr. Mohammed Mozaher and Dr. Sagheer Onaizi for their valuable contribution to this research.

I would like to express my deep thanks to the Center of Research Excellence in Nanotechnology (CENT) for allowing me to use all CENT's facilities during this research. I am very thankful to the CENT director Dr. Zain Yamani for his always support and encouragement. I would like also to thank Dr. Abbas Hakeem for teaching me how to handle many equipment. My thanks also goes to all CENT affiliates; Mr. Idris, Mr. Sanhoop, Dr. Qasem Drmosh, Mr. Anas Karrar, Mr. Mohammed Hassan, Mr. Saheed, Mr. Ibrar and Mr. Qamer.

I am very grateful to my parents, my brothers (Maged, Maher, Fawaz & Safwan), my sisters (Sonia, Ashgan, and Julia), my wife, my cousin Aref, my uncles (Saleh and Mohammad), my father in law, my grandmother and whole family for their prayers and supports.

Last but not least, I would like to thanks my friends and colleagues Mr. GALAL Aqeel, Mr. Madyn, Mr. Saleem, Mr. Ammar, Mr. Mohammad Al-ezzi, Mr. Magd Nadeem, Mr. Abullah Al-madani, Mr. Mohmmad Ameen, Mr. Yahya Al-buri, Mr. Abdullrashid And Mr. Hassan Saleh for their friendness and kindness.

## ABSTRACT

Full Name : [Galal Atef Ahmed Nasser]

Thesis Title : [Synthesis and characterization of cost-effective Chabazite (CHA) zeolite catalysts for the conversion of methanol to olefins (MTO) process]

Major Field : [Chemical Engineering ]

Date of Degree : [December, 2017]

Light olefins ( $C_2^=$ - $C_4^=$ ) are very important intermediates for many processes in the petrochemical industry. Conventionally, they are produced from steam cracking units, alongside other products. Nowadays, the prices of lower olefins are increasing. Other processes which are very selective towards light olefins and depend on sustainable resources are highly required to increase olefins production. The methanol to olefins (MTO) process which is very selective towards ethylene and propylene is a very promising process.

Currently, the MTO process is commercialized and ZSM-5 and SAPO-34 catalysts are known to have excellent activity with different selectivities and deactivation rates. However, the synthesis of these two catalysts requires the use of an organic structure directing agent (OSDA) which makes their preparation methods challenging economically. Thus, this research was devoted to find a cost-effective method to synthesize a novel Chabazite (CHA) catalyst for the MTO reaction.

Two approaches with different molar gel compositions have been followed to fabricate a cost-effective and selective CHA zeolite catalyst. The first approach was the synthesis of an OSDA-free CHA zeolite in the presence of a fluoride ion. While in the second approach, SSZ-13 seed was used to assist the CHA synthesis by utilizing microwave-

assisted hydrothermal synthesis (MAHyS). Several experiments have been conducted to investigate different conditions under which the CHA catalyst was formed. After the successful fabrication of CHA zeolite catalysts, we used different characterization techniques to characterize the prepared catalyst. XRD, NMR and XRF were used to investigate the structure and to measure the elemental compositions. The textural properties, the morphology and the acidity were characterized using nitrogen physisorption, FE-SEM and  $\text{NH}_3$ -TPD, accordingly.

**For the first approach:** A series of cost-effective aluminum-rich chabazite (Al-rich CHA) zeolite with improved textural properties was synthesized without using templates. Herein, we report a detail synthesis method for CHA zeolite without using an organic structure directing agent (OSDA-free). Pure CHA zeolites were successfully synthesized under different gel compositions.. The BET results showed that ion-exchange enhanced the surface area from around  $1 \text{ m}^2/\text{g}$  to around  $485 \text{ m}^2/\text{g}$ . Aging time had a significant influence on the crystallization rate, particles' size and shape. The synthesized CHA zeolite was evaluated in the methanol-to-olefin (MTO) reaction at different reaction temperatures. The conversion was maintained at 100% for 4 h at  $350^\circ\text{C}$  and for 2 h at 400 and  $450^\circ\text{C}$ . The selectivity to lower olefins was correlated to the reaction temperature and time on stream (TOS). The highest olefins selectivity was ca. 93.8 at 180 min TOS and reaction temperature of  $350^\circ\text{C}$ .

**In the Second approach:** Cost-effective aluminum rich (Al-rich) CHA zeolite was synthesized by seed-assisted hydrothermal synthesis under microwave irradiation to shorten the crystallization time. Al-rich CHA zeolite was successfully synthesized within 6 h. The Al CHA was synthesized under different stirring rates and evaluated for the

methanol-to-olefins reaction at three different temperatures in a fixed bed reactor. Boron was incorporated by in-situ synthesis. The XRD pattern revealed that the synthesized CHA was crystalline. The performance evaluation revealed that reaction temperature and TOS affected both the catalyst's stability and selectivity to light olefins. At a lower temperature (350 °C), the Al-rich CHA was more stable and less selective to light olefins at the beginning of the reaction. The selectivity was increased from 41.8% at TOS of 10 min up to 85.0% at TOS of 120 min. In contrast, the selectivities of olefins at TOS of 10 min were 55.0 and ca. 79.6% when the reaction temperatures were 400 °C and 450 °C, respectively. Incorporation of boron only enhanced the olefins selectivity at the initial stages of the reaction. The total olefins' selectivity over the parent CHA was ca. 41.8% and then increased to ca. 71.5% when the CHA was incorporated with boron (Si/B = 13).

## ملخص الرسالة

الأسم الكامل: جلال عاطف أحمد ناصر

عنوان الرسالة: تصنيع وتخصيص مادة الزيوليت من نوع كابازيت والتي أستخدمت كمادة محفزة لعملية تحويل الميثانول الى اوليفينات صغيرة.

التخصص: الهندسة الكيميائية

تاريخ الدرجة العلمية: ديسمبر 2017

تعتبر الأوليفينات الخفيفة من أهم المركبات التي تستخدم لإنتاج العديد من المواد في المصانع البتروكيميائية. إن الطريقة الإعتيادية لإنتاج هذه المركبات هي عن طريق تكسير المركبات الهيدروكاربونية في المصفأة في ظل وجود البخار. وبالنظر الى سعر المركبات الأوليفينية، سنجد أن سعرها في تزايد مستمر، لذلك لابد من وجود عملية بديلة تعتمد على مصادر متجددة وذات إنتقائية عالية لإنتاج الأوليفينات لسد حاجة السوق. وتعتبر عملية تحويل "الميثانول إلى أوليفينات" من أهم العمليات الواعدة التي تعتمد على مصادر متجددة، وتمتاز بانتقائية عالية نحو إنتاج الاوليفينات الخفيفة.

حالياً تم تطبيق عملية تحويل الميثانول الى أوليفينات واقعياً، حيث تستخدم مادتي الـ (ZSM-5) و (SAPO-34) كمواد محفزة لسير العملية. كلا المادتين أثبتت نشاطهما التفاعلي بنسب انتقائية مختلفة، ولكن يدخل في آلية تحضيرهما مركب عضوي يرمز له بـ (OSDA) الذي يجعل طريقة التحضير مكلفة وغير مرغوبة اقتصادياً. لذلك كُرس هذا البحث لإيجاد طريقة اقتصادية ومجدية لتحضير مادة محفزة تدعى كابازيت (Chabazite) والتي ستستخدم في تحويل الميثانول الى اوليفينات خفيفة.

ولتحقيق هدف البحث، عملنا على تصنيع مادة الكابازيت بطريقتين مختلفتين؛ الطريقة الأولى قمنا بتصنيع مادة الكابازيت منخفضة التكلفة في وجود أيون الفلور وغياب OSDA أثناء التصنيع. أما الطريقة الثانية فقمنا بتصنيع الكابازيت بمساعدة كابازيت تم تصنيعه مسبقاً مستغلين اشعاعات الميكرويف أثناء عملية التصنيع. وقمنا بإجراء العديد من التجارب لغرض معرفة تحت أي ظروف يمكن تحضير الكابازيت. بعد ان حضرنا الكابازيت ذو النقاية العالية قمنا بدراسة خصائصه مستخدمين عدة أجهزة؛ حيث تم استخدام جهاز الاشعة السينية (XRD) وجهاز NMR

وجهاز XRF لتحليل البنية التركيبية وقياس نسبة العناصر المكونة للكابازيت، كذلك تم استخدام المجهر الإلكتروني وأدماصص الأمونيا لمعرفة الخصائص التكوينية ودرجة حموضة الكابازيت.

**الطريقة الأولى:** تم تصنيع سلسلة من الزيوليت من نوع كابازيت الغني بالألمنيوم مع تحسن في الخصائص التكوينية دون الحاجة الى استخدام OSDA. حيث أظهرت دراسة الـ BET ان عملية تبادل الايونات قد عززت مساحة السطح من حوالي 1 م<sup>2</sup> / جم الى 485 م<sup>2</sup> / جم. ان عامل الوقت أثناء عملية التحضير كان له دوراً مهم بالتأثير على معدل التبلور وحجم وشكل الجسيمات. وتم اختبار كفاءة المادة في تفاعل تحويل الميثانول الى أوليفينات عند درجة حرارة 350 و 400 و 450 درجة مئوية، حيث أظهرت نتائج التفاعل تحول كامل للميثانول لمدة 4 ساعات عند درجة حرارة 350 و لمدة ساعتين عند درجتى حرارة 400 و 450 درجة مئوية. أما بالنسبة للانتقائية، فقد وجد أنها مرتبطة بكل من درجة الحرارة ووقت التفاعل، فقد لحظ أعلى نسبة إنتقائية حول 93.8 % بعد مرور 180 دقيقة من بدء التفاعل عند 350 درجة مئوية.

**الطريقة الثانية:** تم تصنيع كابازيت رخيص التكلفة في ظل وجود كابازيت مسبق التحضير وذلك باستغلال إشعاعات الميكرويف لتقليل وقت التصنيع، حيث تم الحصول على كابازيت نقي خلال 6 ساعات. الكابازيت المصنع والغني بالألمنيوم تم تحضيره عند معدل تحريك ديناميكي مختلف، ومن ثم تم اختباره في تفاعل تحويل الميثانول الى أوليفينات عند ثلاث درجات حرارية مختلفة. إضافة الى تصنيع كابازيت نقي، تم اضافة عنصر البورون خلال عملية التصنيع لدراسة مدى تأثيره على التفاعل. ولقد أظهرت دراسة الاشعة السينية بان الكابازيت المصنع كان متبلوراً بشكل جيد و مطابقاً تماماً للمرجع. كذلك أظهرت نتائج دراسة التفاعل أن درجة حرارة التفاعل وزمن التفاعل كان لهما تأثيراً كبيراً من حيث الانتقائية والكفاءة، فعندما كانت درجة الحرارة منخفضة ( 350 درجة مئوية) كان الكابازيت أكثر استقراراً لكن أقل إنتقائية، وبالمقابل، عند درجة حرارة أعلى كان الكابازيت أكثر انتقائية لكن أقل استقراراً، حيث زادت الانتقائية من 41.8 % الى 85% عندما زاد وقت التفاعل من 10 دقيقة الى 120 دقيقة، وبعد 10 دقائق من التفاعل كانت الانتقائية للأوليفينات 55% عند درجة حرارة 400 مقارنة بـ 79.6% عندما ارتفعت درجة حرارة التفاعل الى 450 درجة مئوية. الجدير بالذكر ان إضافة عنصر البورون عمل فقط على تحسين الانتقائية في بداية التفاعل.

# CHAPTER 1

## INTRODUCTION

Olefins or alkenes are unsaturated and very active hydrocarbons with a general chemical formula of  $C_nH_{2n}$ . Among these alkenes are light olefins (such as ethylene, propylene and butene), which are very important building blocks for the petrochemical industries as starting materials for manufacturing of polyolefin and for reactions such as oxidation, halogenation and oligomerizations [1]. Additionally, light olefins are used to manufacture fibers, plastic and large number of chemicals such as benzene, isopropyl benzene, styrene, and propylene oxide and epoxy ethane [2, 3]. Thus light olefins are main resources for many derivatives that we daily use in our life [4].

As the world population is keeping in increase and as our life comfort involves the use of more olefins derivatives, the demand for light olefins will grow vastly. In 2013, the demand for ethylene and propylene was 133 and 83 million metric tons, respectively, while the expected demand in 2023 will be 194 million metric tons for ethylene and 126 million metric tons for propylene. With the increasing demand of ethylene and propylene, their price will also keep increasing. **Figure 1** shows the increase in price for ethylene and propylene in the United States for the period of 2007-2014. From **Figure 1**, it's clear that the increase in propylene price is more than of ethylene. This increase is caused by the ethane cracking which produces more ethylene leading to lower supply of propylene.[5]

There are a number of technologies dedicated to produce olefins, however steam cracking (SC) technology is the primarily technology for the production of light olefins. In the SC, naphtha and ethane, which are oil-based derivatives, are cracked in the presence of steam to olefins and other products [1, 6]. Other technologies such as the conversion of methanol to olefins (MTO), the Fischer-Tropsch synthesis, oxidative coupling of methane and catalytic dehydrogenation of light alkane produce olefins with lower capacities [4]. The advantage, disadvantage and the way of each technology works is discussed briefly in chapter 2.

In this section, it is worthy to mention that production of lower olefins using the SC process requires high temperature which consumes huge amount of energy [2]. Also, the amount produced from steam cracking does not meet the world demand of olefins. Thus, alternative routes for the production of light olefins with higher selectivity toward ethylene and propylene are required to meet their growing demand and to ensure sustainable resources. Methanol to olefins (MTO) route is one of the promising processes to increase the production of light olefins with controllable selectivity to either propylene or ethylene, low emission of carbon dioxide and less energy consumption [1, 7]. **Figure 2** shows the amount of methanol used for the production of light olefins. Moreover, MTO process, which is now commercialized, is an excellent alternative process for olefins production because: (I) it is economically favored, (II) it is favored in term of simplicity, (III) environment friendly and (VI) its feedstock is sustainable and does not rely on oil. Hence, MTO process development met a great attention. Thus, our focus in this study is to develop and efficient and cost-effective catalyst for the production of olefins from MTO process.

**Figure 1. Ethylene and Propylene Price in United States since 1990 up to 2010.  
(Vienna/OPEC presentation, 2014)**

**Figure 2. Methanol consumption for the production of olefins in China[5]**

Many type of acidic zeolites framework have been utilized in the literature for the MTO reaction. Among these catalysts are ZSM-5 and SAPO-34 which show excellent performance in the MTO reaction. However, the two catalysts showing different selectivities to olefins and different deactivation rate because they have different topologies and physical properties. ZSM-5, for example, which has a MFI topology is very stable in the MTO reaction but it is not selective as SAPO-34. In contrast, SAPO-34 with CHA topology is more selective to lower olefins but it suffers from the fast deactivation.

The preparation of these catalysts involves the use of templates which are expensive and have negative effect on the environment. This work focuses on the production of light olefins from methanol with high stable and selectivity to lower olefins using cost-effective catalysts. Hence, our attention will be to the zeolite catalysts with the CHA topology. To have cost-effective CHA zeolites, we will focus on the preparation of OSDA-Free CHA.

## 1.1 Objective

The general objective of this research is to fabricate a stable and selective cost-effective CHA zeolite catalyst for the conversion of methanol to light olefins. To achieve that objective, two approaches have been examined for the catalyst fabrication

### **First approach:**

The objective of this approach is to investigate and evaluate the preparation of an OSDA-Free CHA zeolite in the presence of Fluoride ion. In more details:

1. Hydrothermally synthesize CHA zeolite without using any organic structure directing agent (OSDA).
2. Investigate the effect of altering gel composition on the catalysts crystallinity, morphology, Si /Al ratio and particles' size and shape.
3. Study the effect of metal incorporation on the CHA performance in the MTO reaction.
4. Characterize the synthesized catalysts using different characterization techniques.
5. Test the prepared catalysts in a fixed bed reactor to study their activity, selectivity and stability in the conversion of MTO process

**Second approach:**

In this approach, microwave irradiation was used to synthesize an OSDA-free CHA zeolites from an amorphous aluminosilicate gel in the presence of a seed. In more details

1. Synthesize of pure CHA zeolite without using templates.
2. Optimize the synthesis time.
3. Investigate the effect of B incorporation.
4. Characterize the synthesized catalysts using different characterization techniques.
5. Evaluate the performance of the prepared zeolite in MTO reaction at different temperatures.

## 1.2 Methodology

The plan set for achieving the objective of this work is summarized in **Figure 3**. As mentioned in the objective section of this document, there will be two approaches for the synthesis of cost-effective catalysts without using any templates. In the first approach, the CHA zeolite catalyst was synthesized from basic chemicals following a cost-effective method that excludes the use of an OSDA. In the synthesis of the catalysts, large numbers of experiments were conducted to explore the effect of different compositions of the gel on the crystallinity and physical properties of CHA zeolite. Finally, the catalyst activity was evaluated in a fixed bed reactor for conversion of methanol to olefins.

The second approach was dedicated to synthesize CHA zeolite using microwave heating and SSZ-13 seed to assist the formation of CHA phase. In this method, the preparation method of CHA zeolite was adapted from literature but with shorter crystallization time.

**Figure 3. A summary for the methodology followed to achieve the work**

## CHAPTER 2

### LITERATURE REVIEW

#### 2.1 MTO process

The process of methanol to olefins is a very important process for the production of light olefins from non-oil routes such as coal and natural gas through the conversion of methanol [8]. Even the feedstock to the MTO process can be obtained from oil, MTO process works as a bridge between modern industries and coal, biomass and natural gas [9, 10]. The potential importance of MTO process is that two or more carbons are formed from a single carbon which can be derived from different resources [1]. Historically, the first report for methanol conversion to hydrocarbons and ether as side products is dating back to 1880 [11]. However, the importance of methanol conversion to the industry was appeared in the early of 1970s by the discovery of Mobiles researchers.

Prior to MTO process, methanol is firstly derived from syngas (a mixture of carbon dioxide and hydrogen) which is produced from the gasification of coal or from the steam reforming of natural gas [12]. **Figure 4** shows how methanol is produced from non-oil resources. Then the methanol is transformed to an equilibrium mixture of dimethyl ether (DME), methanol and water. Finally, the equilibrium mixture is converted to hydrocarbons (gasoline or light olefins) depending on the type of catalysts used and the process conditions [12]. For example, at around 400 °C and an optimum partial pressure of methanol, the methanol to gasoline (MTG) reaction at the presence of ZSM-5 catalyst takes place. These conditions are optimum for the transformations of olefins to aromatics

and paraffins. Altering the reaction temperature and changing the type of catalyst favors MTO or methanol to propylene (MTP) processes. A detail description of the MTO reaction mechanism is given in section 2.5 of this document.

**Figure 4. Hydrocarbons production through methanol.**

### 2.1.1 MTO History

During the first and the second oil crises, mobile increased its effort in the development of methanol conversion to gasoline (MTG) process. As a result of this, MTO process was discovered by chance when Mobile researchers in 1970s were trying to find new routes to produce gasoline with high octane-number over HZSM-5 [13-15]. In their strategy, they were feeding methanol and isobutene hoping that a methyl carbene or methyl cation will form and actively react with the alkane to form longer chain of alkanes. However, they noticed that the products were a liquid consisting of gasoline and a gas containing aromatics and paraffins. The researcher found that the products were formed by the conversion of methanol. This was proofed by mass balance on isobutene which was not consumed during the reaction. Additionally, when the pure methanol was feeded alone,

they found the same products. This led to the discovery of the conversion of methanol to hydrocarbons (MTG) process [14, 15].

Since MTO process has been firstly proposed by Mobile Oil in 1970s, many studies have been conducted to develop the process by studying the kinetic of the process, catalysts synthesis and establishing research and development centers[9]. Studying or fabricating catalysts with higher efficiency, which will decrease the operating cost of the MTO process, is another important point in the development of MTO process [15]. The type of the catalysts used in the MTO process is solid acidic catalysts. Many types of zeolites have been evaluated in the MTO process; however, ZSM-5 and SAPO-34 were proven to have excellent activities in the MTO process.

## 2.2 Technologies of olefins production from methanol

The attention to methanol conversions was initiated after the first and second oil crises in 1973 and 1979 for the purpose of gasoline production, methanol-to-gasoline (MTG) [16]. In the MTG process, olefins were as intermediate products in the production of gasoline. Later, Mobile produced olefins as primary products while gasoline as secondary products. Then, this process has been extended to olefins oligomerization to produce combined products of gasoline and diesel as shown in **Figure 5**.

**Figure 5. The conversion of olefins to gasoline and diesel, the process called Mobile olefins to gasoline and distillate process (MOGD)[16].**

After that, a number of processes have been developed. Herein, we will give a brief summary of technologies used to produce light olefins from methanol.

### 2.2.1 INEOS or UOP/Hydro MTO process

In 1995, UOP and Norsk Hydro (now INEOS) developed the MTO process over SAP-34 catalyst [16-18]. They developed a pilot plant with a capacity of 0.75 [18] or 0.9 [17] ton per a day of methanol feed using fluidized bed reactor at Hydro in Norway. Later in 2009, this process was combined with a process from TOTAL called olefin cracking process (OCP) for further enhancement of propylene and ethylene selectivity as shown in **Figure 6**. The capacity of this combined process was around 10 tpd of methanol feed. In 2013, a first commercial MTO plant which produces 295 kt/y of lower olefins was built in Nanjing, China.

**Figure 6. Schematic diagram of the combined INEOS and OCP process[18].**

### 2.2.2 Lurgi MTP process

The Lurgi MTP process is the same as the UOP's MTO process, except a special attention was paid to propylene selectivity by using ZSM-5 catalysts. The reaction temperature is ranging between 450 and 500 °C using a fixed bed reactor. For the purpose of maximizing the propene selectivity, C<sub>2</sub> and C<sub>4</sub> olefins were recycled back to the reactor as shown in **Figure 7**. The process was designed in such a way that the fixed-bed reactors are in parallel to allow regeneration from time to time. This process has been commercialized in China in 2010 with a capacity ca. 500 kt per year of propene and 185 kt per year gasoline. [16-18]

**Figure 7. The Lari MTP process[16].**

### 2.2.3 JGC/Mitsubishi DTP process

In 2007, the Japan Gasoline company (JGC) and the Mitsubishi, together, have developed another process for propylene production called Dominant Technology for Propylene (DTP). The catalyst used in this process is ZSM-5 modified with calcium. DME or a mixture of DME and methanol is feeded to a series of fixed-bed reactors operating at 500 °C and 1 atm [17].

## 2.3 Zeolites

Zeolites, which were discovered in 1756 by the Swedish scientist Axel Fredrik, are microporous inorganic crystalline solid materials. Zeolites were discovered when Fredrik was heating unknown minerals and he noticed a generation of steam from these minerals [19]. After this accident, Fredrik named these materials as “Zeolites” which has been derived from two Greek words; “ζέω (zéō) mean to boil” and “λίθος (líthos) means stone”. Thus, a basic definition of zeolites and based on translation is “the stones that boil” [20].

Zeolites are basically formed from the tetrahedral of  $TO_4$ , where T can be Al, Si, P, B, Ge, Zn etc. [20]. In most cases the T is Si and Al, thus an explanation of zeolites framework will be given based on the Si and Al. **Figure 8** shows the  $AlO_4$  and  $SiO_4$  tetrahedral and how they are connected to form the basic network of zeolite framework. Aluminum (Al) has a 3 valance electron and appears in its cationic form as  $Al^{+3}$  while Silicon has 4 valance electrons and appears as  $Si^{+4}$ . Oxygen which works as a bridge between alumina and silica has two valance electrons and its anion form is  $O^{-2}$ . Thus, oxygen will bond with two atoms, Si and Al, to form a structural as shown in **Figure 8 a**. This binding will lead to the appearance of a negative charge on the Al (**Figure 6 a**) but this anion tends to forms on the oxygen atom as shown in **Figure 8 b**. To have the structure to be neutral, a cation must compensate the negative charge. The cation could be  $Ca^{+1}$ ,  $Na^{+1}$ ,  $H^{+1}$ ,  $K^{+1}$  etc.

**Figure 8. Basic structure of zeolites, tetrahedral of  $\text{AlO}_4$  and  $\text{SiO}_4$**

### 2.3.1 History of zeolite

The history of zeolite is back to the discovery date of the natural zeolite in 1756 [21]. Since that time, extensive application of natural zeolites led to the further discovery of their intrinsic properties such as the reversible water adsorption capacity. Later, in 19th century, scientists found that zeolites possessing the ion-exchanged property with metallic cations under similar properties. At that time, scientist recognized that zeolites can adsorb ethanol, formic acid vapor, water and methanol, and cannot easily adsorb benzene, diethyl ether and acetone. This property made scientist to recognize the importance of the zeolites in adsorption applications.

In nature, zeolites firstly were found in cavities and vugs of basalts. A time later, namely in the 19th century, zeolites were found in the sedimentary rocks. The formation of zeolites is recognized by a certain genetic forms, mentioned somewhere else [21]. The intense investigation to minerals resulted in the discovery of more zeolites; more than 40 types of natural zeolites up to now have been discovered. Chabazite, Clinoptilolite, Mordenite, Heulandite and Stilbite, to name but a few, are examples of natural zeolites.

Nowadays, natural zeolites are used for water and gas separation, softening of water, drying ...etc [21].

### **2.3.2 Structural building units of zeolites**

The structure of zeolites is consisting of several building units. The primary building unit of zeolites is the tetrahedra of  $\text{AlO}_4$ ,  $\text{SiO}_4$  (aluminosilicate zeolites) and  $\text{PO}_4$  (in the case of aluminophosphate or silicoaluminophosphate) [22]. More complex building units of zeolites are formed by the combination of the primary building units. The 4-corner sharing of the tetrahedra results in a microporous and low framework density. The framework density is defined as the number of T atoms per 1000 Å [20, 23]. For understanding the structure of zeolites, it can be viewed as composite of rings which are formed by a number of tetrahedra. The name of the ring is given based on the number of tetrahedral it contains. For example, the four ring (4-ring) is consisting of 4 tetrahedra. Other tetrahedral n-rings are exists, where n can be 4, 6, 6, 10 or 12 tetrahedra as shown

**Figure 9.**

Figure 9. Secondary building units of zeolites [21].

### 2.3.3 Composition of zeolites framework

After a brief discussion about zeolites building units in which the basic building units consisting of the  $\text{TO}_4$  tetrahedra, someone may ask how the tetrahedra and ions are arranged in the zeolites framework? In silicoaluminate zeolites, bonding of the Al and Si tetrahedral follow the criterion depicted in **Figure 10**. Arrangement in **Figure 10 A, b, c, d, e** and **f** is possible, while the arrangement in **Figure 10 a** is unlikely to occur due to Lowenstein's rule constraint [22]. This means that Al-O-Al is impossible [24].

Figure 10. Possible arrangement of  $\text{SiO}_4$  and  $\text{AlO}_4$  tetrahedra; the oxygen atom that connect between Si and Si or Si and Al is not shown.

### 2.3.4 Acidity of zeolites

Zeolites are very acidic solid catalysts which have been utilized in the reactions that require acidity such as cracking and MTO process. The source of acidity in zeolite is raised from the orientation of their structure. The basic building unit of zeolites is the tetrahedral of alumina ( $\text{AlO}_4$ )<sup>-5</sup> and silica ( $\text{SiO}_4$ )<sup>-4</sup>. These tetrahedral are joined together to form Si-O-Si or Si-O-Al bond. The Si-O-Al is missing a positive charge, a cation, to make it neutral. The cation can be any type of cations (such as  $\text{K}^{1+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{1+}$ ,  $\text{Na}^{1+}$ ,  $\text{NH}_4^{1+}$ ) which can be exchanged by a desired one [25]. When the cation is a proton  $\text{H}^+$ , the proton will attach to the oxygen to form hydroxyl group bridge between Si and Al (Si-OH-Al). This hydroxyl group is the responsible for the Brønsted acid sites which are used for cracking and conversion of methanol to hydrocarbons [26, 27]. Another hydroxyl groups are do exist in the zeolites structure. The Si-OH which called as the silanol group is found at the termination or defects in the zeolite framework. The Al-OH group is found in the case of extra framework of aluminum [25]. In fact, there are different forms of Al which can be present as extra framework in zeolites such as  $\text{Al}_2\text{O}_3$ ,  $\text{AlOOH}$ ,  $\text{Al}(\text{OH})^{2+}$ ,  $\text{Al}(\text{OH})^{2+}$  [28].

### 2.3.5 CHA frameworks

The frameworks of CHA zeolite is consisting of four rings (4R), six rings (6R) and eight rings (8R). In CHA framework, a series of double six rings (D6R) is linked by a series of 4R that are skewed to form a cage with a pore opening of 8R as shown in **Figure 11**. The cations present in the framework of CHA zeolite can be located at different positions. They can be in the center of the D6R, in the center of the cage or near to the moth opening of the 8R [29]. The location of the ions, usually after ion-exchange the proton

ion, can be determined using infrared and NMR analysis. It has been found that the stretching and chemical shift of the OH bridge differ by the size of the pore where the ion presents [29].

**Figure 11. Arrangement of 4R and 6R to form of CHA cavity (IZA).**

### **2.3.6 Synthesis of zeolites**

As mentioned earlier, zeolites can be found in nature or can be synthesized in the lab. Zeolites which are found in nature are called natural zeolites and tend to have impurities that limit their application as catalysts in many reactions [30-32]. However, pure zeolites with desired properties can be synthesized in the lab. The first batch of zeolite synthesis is dated back to 1950s [33]. There are different methods for the synthesis of zeolites; hydrothermal method, vapor phase transport and steam assisted conversion method. The hydrothermal method involves three main steps; (i) the mixing of amorphous reactants such as alumina, silica, and a cation at room temperature, (ii) heating the mixture at a

temperature ranging from 70 up to 200 °C in a Teflon-lined stainless steel, this process called crystallization, (iii) separation and washing the crystallized zeolites [33]. Although, the steps seem to be easy to follow, a number of factors strongly affect the formation of zeolites framework, morphology, crystal size and composition. For example, the presence of structure directing agent (an organic chemical used to direct the structure formation), type of alkaline metals and source of alumina and silica all have strong influences on the synthesis. For more detail regarding zeolite synthesis, a reader is recommended to read other sources [33, 34].

**Figure 12. Vapor phase transport (a) and steam-assisted conversion (b) methods of zeolites synthesis [35].**

### 2.3.7 Characterization of zeolites

There is a number of sophisticated equipment uses to characterize different properties of zeolites. For example, the structure of zeolites can be investigated using X-ray diffraction (XRD), Nuclear Magnetic Resonance (NMR) spectroscopy and X-ray fluorescence (XRF). Field-emission scanning electron microscopy (Fe-SEM) and energy dispersive X-ray (EDX) are used for the morphology analysis. The acidity, surface area and pore volume distribution are measured by the Ammonia-Temperature Program Desorption (NH<sub>3</sub>-TPD), the pyridine adsorption in the Fourier transform infrared spectroscopy (FT-IR) and N<sub>2</sub> adsorption/desorption isotherm, accordingly.

In this section, a brief background about the equipment will be presented, and the experimental procedure for each equipment will be explained when it is used throughout the work.

#### *Surface area analysis*

Brunauer–Emmett–Teller (BET) theory is one of the most popular methods used for surface area measurement of solid materials. The Langmuir isotherm is the starting point of the BET theory. Calculation of the surface area is based on adsorption a gas (usually nitrogen) at liquefied temperature. Prior the analysis, the samples are degassed at an appropriate temperature in order to remove any adsorbed gasses or impurities.

The following equation is called BET equation:

$$\frac{1}{v[(p_0/p) - 1]} = \frac{c - 1}{v_m c} \left( \frac{p}{p_0} \right) + \frac{1}{v_m c}$$

Eq. 1

Where:  $v$  is the amount of adsorbed gas,  $p_0$  the equilibrium pressure of the adsorbate gas,  $p$  the saturation pressure,  $p_0/p$  the relative pressure,  $v_m$  is the quantity of gas adsorbed by one layer and  $c$  the BET constant

From above equation, the term  $\frac{1}{v[(p_0/p)-1]}$  can be plotted against  $\frac{p}{p_0}$  to give a straight line with a slope  $(A) = \frac{c-1}{v_m c}$  and intercept  $(I) = \frac{1}{v_m c}$ . From the slope and intercept, the adsorbed gas quantity and BET constant can be calculated.

The total surface area is calculated from:

$S_{\text{total}} = \frac{(v_m N s)}{V}$  where  $N$  is Avogadro's number,  $s$  the cross section of the gas and  $V$  molar volume of the adsorbate gas .

While the specific surface area is calculated from:

$S_{\text{BET}} = \frac{S_{\text{total}}}{a}$  where  $a$  is the mass of the adsorbent .

### ***Nuclear Magnetic Resonance (NMR) spectroscopy***

The Nuclear Magnetic Resonance (NMR) spectroscopy is the technique used to investigate the structure of zeolites. It determines the orientation of the compounds in the structure; the distribution of aluminum, silicon, phosphorous and any other elements incorporated in the zeolites framework [24]. But, what is the concept behind NMR?

The concept behind NMR is that a magnetic field is applied to the nuclei of a certain element and then measure the amount of energy required to put different nuclei in

resonance. Resonance is a phenomenon in which an external object or a vibrating object makes another object to oscillate; matching of frequencies. The amount of energy required to put an object in resonance is effect by the nuclei environment, shielded or de-shielded environment. Then the NMR provides a signal indicating the amount of energy to put nuclei in resonance. Each nuclei will have a unique signal.

For zeolites, mainly  $^{27}\text{Al}$ , and  $^{29}\text{Si}$  solid state NMR are used to study the coordination of aluminum and silicon tetrahedral. For  $^{29}\text{Si}$  NMR, 5 peaks can beaks, which are corresponding to the five coordination of Si as shown in **Figure 13**, can be detected [24, 36].

Figure 13. NMR peaks positions corresponding to different arrangement of Si orientation[36].

### *Fourier series –infrared (FT-IR) and Pyridine adsorption*

To understand the IR spectroscopy, it's preferable to have some key points about functional group and frequencies. Different Functional groups wag, bend and stretch at different frequencies. Thus, the functional group will adsorb light frequencies that match the frequencies of lagging, stretching and bending. For well understanding, let us assume molecule A having this functional group (O=C), the double bond will stretch at a frequency of , say, 3 Hz while it lag at 5 Hz. If a source of light is passed through this molecule at a frequency of 2 Hz, then the detector will detect the same frequency. Therefore, we will have 100% transmission of the light. Then, if the frequency of the light is changed to 3 or 5 Hz which is the same as the stretching and lagging frequency, the transmission of light will be close to zero. Thereafter, a graph representing the transmission versus the frequencies can be generated and adsorption bands can be seen,

**Figure 14.**

**Figure 14. Generated figure to explain the concept of IR**

### ***X-ray diffraction***

XRD is an analytical technique used to identify a crystalline material. But what is x-ray and what are the benefits of it in characterizing solid materials? X-ray is an electromagnetic radiation with a wavelength of ca. 10 nm to  $10^{-1}$  nm. The XRD provide information about the phase, grain size, strain and crystal defects. The XRD consists of the x-ray tube, sample holder and x-ray detector. The x-ray is generated in a cathode tube where a filament is being heated to generate electrons, which are accelerated by a applying a voltage difference. The produced electrons hit a sample and causes a dislodge to electrons in the inner shell so that an x-ray which is a characteristic of the sample is being produced and recorded by a detector. [37]

The crystallite size of a material can be estimated using Scherre equation, Eq. 2.

$$t = \frac{0.9\lambda}{\beta \cos \theta} \quad \text{Eq. 2}$$

Where  $\lambda$  is the wavelength,  $\beta$  is the width of the peak at the middle of the peak intensity and  $\theta$  is the diffraction angle.

### ***Gas Chromatography (GC)***

Chromatography is a wide topic; however a brief introduction on GC will be given. Generally, the GC is used for materials that are volatile and hydrophobic. The system of GC is consisting of three main parts; the injector, column, and detector. The injector is a place where a sample is injected and got mixed with the carrier gas (the mobile phase). Column is a very thin long narrow tube that is coiled to form cylinder shape like. The

column is placed inside an oven to ensure that the analytes (desired samples to be separated) in a vapor form. The analyte are then mounted by the end of the column to a detector. Detector is a device used to sense the elutes (the outlet of the column). There are many types of detectors; some detectors are used for one purpose, ex. to calculate retention time, and some other for multifunction. Usually, GCs are equipped with more than one detector which is ordered in series.

### ***Field-Emission scanning electronic microscope (FE-SEM)***

The electron microscope is a sophisticated type of microscopes in which a beam of electrons are used to give an image about a sample. The electronic microscope gives better magnification and resolution than light microscope. **Figure 15** shows the main components of the SEM. In SEM, beam of electrons, which pass through a condenser lens to make a narrow beam, is scanned over a sample. Beam of electrons bombard the sample emit secondary electrons which are then detected by a detector to give an image about the sample.

Figure 15. Main component of SEM [38]

### *Energy Dispersive X-ray (EDX)*

The EDX is provided with the FE-SEM with different detector to detects the x-ray emitted from the sample.

## 2.4 MTO catalysts

Methanol is easily converted into hydrocarbons over solid acidic catalysts. Thus, several types of acidic zeolites in the literature with different topology such as DDR [7, 39], ERI, LTA, UFI, [40] MFI and CHA have been studied in the MTO reaction. Chabazite zeolites are exhibiting an excellent activity in the MTO reaction. However, the solid acidic zeolites SAPO-34 and ZSM-5 are the two catalysts that have been applied in the industry. ZSM-5 with MFI topology is very well known and active catalyst in many reactions, MTO reaction is an example. However, ZSM-5 is less selective towards light olefins and gives wide range of hydrocarbons due to the relative large pore size and small cage size. On the other hand, SAPO-34 with the CHA topology is very active and has higher selectivity to lower olefins.

OSDA free synthesis of CHA zeolite have been reported by the conversion of FAU zeolite [41-43] or using seed assisted hydrothermal synthesis [44]. Fabricating of CHA zeolite without using OSDA resulted in low Si/Al ratio (Si/Al less than 3). The low silica zeolite decreases the activity of the CHA zeolites. However, the low silica CHA can be post-treated to reduce the alumina content. Ji et al prepared CHA zeolite by hydrothermal conversion of Y-zeolite and the post treated using steam and acid to remove the alumina from the CHA framework [41]. In their work, they steamed the as-synthesized CHA (Si/Al =2.4) at different temperature to get CHA with different Si/Al ratio. The dealuminated CHA showed better activity in the MTO reaction than the parent CHA; an increase in the conversion and selectivity to olefins.

Topology of the catalysts (pore and cage size and cage opening) and acidity have strong influence on the selectivity of lower olefins. Reaction temperature also affects the the

selectivity of lower olefins and methanol conversion. In the following section, we will investigate how acidity, topology and temperature influence the conversion, lifetime of the catalysts and selectivity to light olefins.

**Table 1. Different templates used for the synthesis of SSZ-13 CHA zeolites**

Template Name	Type of framework	Preparation method*	Applications	Crystallization time	Crys. T( °C)	Ref.
<b>Copper complex (Cu<sup>2+</sup> and tetraethylenepentamine, Cu-TEPA)</b>	Cu-SSZ-13	A	SCR	3-6 d	140	[45, 46]

<b>Seed +benzyl trimethylammonium</b>	SSZ-13	J	-	2,4	160	[54]
<b>Cu-TEPA</b>	SSZ-13	K	SCR	4	140	[55]

\*: See the appendix for the preparation detail.

### **2.4.1 Effect of reaction temperature on MTO catalyst activity**

The effect of temperature on the conversion and selectivity to lower olefins is summarized in **Table 2**. The effect of reaction temperature is linked to the type of framework. Frameworks with larger pores and cages size such as ZSM-5 shows higher stability at higher temperatures, while small pores zeolites deactivate quickly as the reaction temperature increases.

**Table 2. Selectivity to light olefins and conversion of methanol at different temperatures over different type of catalysts**

catalysts	Rxn. Temperature (°C)	Pressure (atm)	Time on Stream (minutes)	WHSV (h <sup>-1</sup> )	Conversion (%)	Selectivity to olefins	Selectivity to propylene	Selectivity to ethylene	Ref.

### 2.4.2 Effect of topology on MTO reaction

In general, the reactions that use heterogeneous catalysts are affected by the surface area, pore entrance size, acidity, and particle size. For example zeolites such as LTA, ERI, UFI and CHA with 8 member-ring pore entrance show excellent selectivity toward light olefins in the MTO reaction. The small pore entrance in zeolites prevents the transfer of larger molecules (ex. Branched aliphatic and aromatic hydrocarbons) and thus increases the olefins selectivity. However, these types of zeolites framework differ in activity as a result of the difference in their cage size. Large molecules such as poly-methyl benzene are formed inside the cages and work as active intermediates in the formation of the light olefins. But the extra condensation of these intermediate to cyclic hydrocarbons cause catalyst deactivation as a results of the blockage of acid sites, reduction the active intermediates and limiting the diffusion of the products by the cyclic hydrocarbons.

**Figure 16** shows the cage size of different zeolites framework while **Figure 17** shows the products distribution of different zeolites framework at the same reaction conditions. It is very obvious from the two figures that the deactivation is related to the cage size, for example CHA which has the smallest cage size showed lower products distribution because the small cage hinder the further condensation of poly methylbenzene.[40, 56]

Figure 16. Shape and size of different catalyst topology used in the MTO conversion [46]

Figure 17. Chromatograms explaining the effect of different topologies on the products distribution; reaction was done under same conditions ( $T = 400\text{ }^{\circ}\text{C}$ ,  $\text{WHSV} = 2\text{ h}^{-1}$  [57]).

### 2.4.3 Effect of acidity on MTO reaction

Acidity of catalysts plays a very important role in the selectivity of products and conversion of reactants in many reactions. Zeolites which are acidic catalysts possess different densities and strength of acid sites. Some frameworks of different zeolites or even the same type of zeolite has varying amount acid sites strength and density. However, for certain reactions, acidity is needed to be reduced. This can be achieved by leaching the alumina from zeolites' framework or by the attachment of metals. Removing the alumina can be by done by steam treatment at elevated temperature (for example 500-700 °C) or by treatment the samples in acidic medium.

#### *Attachment of metals*

The selectivity towards light olefins was increased when iron and phosphorous have been impregnated over ZSM-5. The presence of phosphorous and iron on ZSM-5 decreased the acidity and thus ceased the olefins conversion to paraffin and aromatics. However, the selectivity to olefins over SAPOO-34 is relatively high due to its 8 MR pore entrance and the cage size which works to maintain active intermediates that are responsible for light olefins production. Even though, SAPO-34 showing higher selectivity to olefins, it suffers from the deactivation as a result of nonreactive intermediate formation.[40]

#### *Acid strength:*

Acid strength and density have a great effect on methanol conversion, stability of the catalyst and selectivity to light olefins. Blenken et al. [58] studied the effect of acid strength on the stability and selectivity toward olefins by using two different catalysts with the same topology; SSZ-13 and SAPO-34. The two catalysts were evaluated at different range of temperature (300 - 425°C) to investigate the influence of temperature

on the catalysts lifetime. The temperature found to have an influence on the conversion of methanol for both type of catalysts. The optimum temperature for SAPO-34 was found to be 400 °C, while H-SSZ-13 was between 300 and 350 °C. At lower temperature, SSZ-13 was more stable than SAPO-34, while at higher temperature, SAPO-34 was more stable. This could be because of the strong acidity of the H-SSZ-13 catalyst.

The selectivity of the two catalysts, SSZ-13 and SAPO-34, to propylene and ethylene is shown in **Figure 18**. The SSZ-13 catalyst with strong acidity had higher ratio of ethane to propylene ( $C_2^= / C_3^=$ ). At a temperature of 375 and 400 °C with a 100% conversion both catalyst, had almost the same selectivity. However, when the conversion was slightly decreased, SSZ-13 showed higher selectivity to ethylene. This increase in selectivity of SSZ-13 to ethylene was explained by the diffusion limitation induced by the coke formation which was larger in the case of SSZ-13 catalyst. Ethylene molecules is smaller than propylene, thus it is easier for ethylene to diffuse than propylene when coke is formed. [58]

**Figure 18. Effect of acid strength on selectivity of light olefins; H-SSZ-13 is more acidic than H-SAPO-34 [45]**

Q. Zhu et al. [50] prepared CHA zeolite using two different methods with different strength of acidity. CHA with low acid site ( $\text{Si}/\text{Al} = 2.4$ ) was prepared by the conversion of FAU zeolite and CHA with stronger acid sites ( $\text{Si}/\text{Al} = 14, 24, 38$  and  $67$ ) were prepared by using organic structure directing agent (OSDA). As it shown in **Figure 19**, strong and weak acid are related to the Al content in the zeolites framework. CHA with low  $\text{Si}/\text{Al}$  ratio ( $2.4$ ) exhibited weak acidity, while CHA with higher  $\text{Si}/\text{Al}$  ratio had strong acid

## 2.5 Reaction Mechanism of MTO process

The mechanism of the conversion of methanol to olefins is very complicated. It has been mentioned earlier that MTO was discovered by chance during the enhancement of the MTG process. Thus, to understand the reaction mechanism of olefins formation from methanol, it is preferable to study the reaction mechanism of methanol conversion to hydrocarbons (MTH) in general. After the discovery of MTH process, the formation of the first C-C bond and the reaction mechanism under which methanol is converted to hydrocarbons are the two points that are not well understood [60]. However, the general apparent reaction mechanism of the MTH process is consisting of three main steps [17, 61]:

- Dehydration of methanol to DME.
- Converting the methanol-DME- H<sub>2</sub>O equilibrium to olefins (Formation of first C-C bond).
- Conversion of olefins to other hydrocarbons such as naphthenes, higher olefins, paraffins, and aromatics.

### 2.5.1 Dehydration of methanol to DME

Methanol is easily dehydrated into DME over acidic zeolites. As shown in **Figure 20**, methanol is firstly adsorbed (irreversibly) to the hydrogen on the hydroxyl bridge of a catalyst to form methoxonium ion which is a protonated form of the methanol [61]. The formation of methoxonium ion process is very fast and has no energy barrier; a proof of this has been reported somewhere else [62] using the density functional theory calculation. Then, the protonated methanol is dehydrated to form surface methoxy species ( $\text{CH}_3^+$ ) which reacts with methanol to form protonated DME (dimethyloxonium ion). Finally, the dimethyloxonium ion is deprotonated to form DME.

**Figure 20.** Reaction mechanism of the dehydration of methanol to DME over zeolite catalyst [50]

### 2.5.2 Formation of the first C-C bond

The formation of the first C-C bond is the limiting step in the MTO mechanism [17]. All reaction mechanisms that have been proposed for the formation of the first C-C bond can be classified into three main methods; the direct coupling of the first carbon (methanol or DME), indirect coupling of the first carbon and the autocatalytic reaction [16]. Herein, we will discuss each method.

There are more than 20 mechanisms explaining the direct coupling of the first C-C bond [16], but carbocations, oxonium ylides, carbenes and free radicals mechanisms are the most popular mechanisms in literature. Thus, we will briefly explore how each mechanism works.

#### *The carbene mechanism:*

The mechanism involves the formation of carbenes by the elimination of water from methanol in the presence of acidic sites as explained in Eq. 3.

Now, how can the generated carbene form the first C-C bond? At the beginning, it has been stated that after the carbene formation, carbenes undergo polymerization to form alkenes. But later on, it was figured out that the carbenes attack the C-O bond of either DME or methanol to form the first carbon-carbon bond [17].

### ***Oxonium ylide mechanism***

In this mechanism, trimethyloxonium ion is formed from the methylation of DME over Brønsted acid sites. Then the base sites deprotonate the trimethyloxonium ion to form dimethyloxonium methyllide which goes through what is called Stevens rearrangement producing methylethene which can be converted to ethylene.

### ***Free radical***

The direct pairing of first carbon fails due to a number of reasons. The most important reason is that it has been found that the pairing rate of the adsorbed methanol in catalyst pores was incomparable to the hydrocarbons formation [63]. Furthermore, the activation energy for the direct coupling was relatively high, around 200 KJ/mol. Moreover, Songe et al.[64] used a very pure reactants, carrier gas and catalyst from any type of C-C bond. They found that the initial methanol conversion was very small. This emphasize that the direct coupling of the first C-C bond is unlikely especially in what is called “induction period”, the induction period is the period in which conversion of methanol increases with TOS.

Ethylene is formed by through the aromatics intermediate while propylene is formed through olefins methylation and cracking reactions [65]. Thus this supports the dual cycle mechanism; the methylation responsible for propylene formation and the aromatic cycle responsible for the formation of aromatics, ethylene and catalyst deactivation. The acidity of the catalyst plays an important role in suppression of the aromatic cycle and promotion of alkene cycle [66].

The autocatalytic concept in the MTH process reaction mechanism was the stepping stone toward the indirect coupling of the first C-C bond formation. Autocatalysis means that the presence of small amount of products gives rise to rate of conversion improvement. The indirect reaction bonding mechanism was firstly proposed by Dessau and co-worker [67, 68]. In their mechanism, they proposed as there are at least some ethylene molecules or other higher olefins that are produced during the induction period, cracking and consecutive methylation take place to produce olefins [67]. Another work by Mole et. al. [69] in which they co-fed aromatics which caused an enhancement in the methanol conversion. However, Dahl and Kolboe [70] concluded that addition of propylene and ethylene to the feed over SAPO-34 catalyst did not have strong effect on the methanol conversion, and most of the produced light olefins were from the methanol conversion rather than the feeded olefins. This poor performance of alkenes over SAPO-34 led to what is called “Hydrocarbon-pool”.

### ***Hydrocarbone pool Mechanism***

The organic species (such as polymethylbenzene), which are trapped in the zeolites' framework, are known as the so called “Hydrocarbon pool”. The hydrocarbon pool species work as reaction centers. These centers are repeatedly methylated by methanol followed by splitting of alkenes such as ethylene or propylene. The reaction centers differed with the type of zeolite structure, for example penta and hexamethylbenzene are more active than lower methylbenzene in SAPO-34 and BET zeolites. In contrast to SAPO-34 and BET zeolites, lower methylbenzene found to be more active in ZSM-5 due to the narrow channels. When the aromatic base cycle and alkene base cycle work simultaneously, it called the dual cycle concept.[57]

## CHAPTER 3

### **OSDA-free chabazite (CHA) zeolite synthesized from amorphous aluminosilicate gel in the presence of fluoride for selective methanol-to-olefins**

#### **Abstract**

A series of cost-effective aluminum-rich chabazite (Al-rich CHA) zeolite with improved textural properties has been synthesized without using templates. Herein, we report a detail synthesis method for CHA zeolite without using an organic structure directing agent (OSDA-free). Pure CHA zeolites were successfully synthesized under different gel compositions. The prepared CHA samples were characterized using different characterization techniques. The crystallinity, the textural properties, the morphology and the acidity were characterized using X-ray diffraction (XRD), nitrogen physisorption, field-emission scanning electron microscopy (SEM) and ammonium temperature programming desorption (NH<sub>3</sub>-TPD), accordingly. The BET results showed that ion-exchange enhanced the surface area from around 1 m<sup>2</sup>/g to around 485 m<sup>2</sup>/g. Aging time had a significant influences on the crystallization rate, particles' size and shape. The synthesized CHA zeolite was evaluated in the methanol-to-olefin (MTO) reaction at different reaction temperatures. The Conversion was maintained at 100% for 4 h at 350 °C and for 2 h at 400 and 450 °C. The selectivity to lower olefins was correlated to the reaction temperature and time on stream (TOS). The highest olefins selectivity was ca. 93.8 at 180 min TOS and reaction temperature of 350 °C.

### 3.1 Introduction

Zeolites are microporous crystalline solid acidic materials with channels and cavities size ranging from 0.3 to 1.5 nm [33]. Zeolites are crucial materials and due to their distinct properties have wide a range of applications in industry as adsorbents, catalysts and detergents [19, 33]. There are more than 232 zeolites frameworks recorded in the International Zeolite Association (IZA). The structure of the zeolites' framework is generally consisting of several building units. The primary building unit of zeolites is the tetrahedra of  $\text{AlO}_4$ ,  $\text{SiO}_4$  (aluminosilicate zeolites) and  $\text{PO}_4$  in the case of silicoaluminophosphate zeolites [22]. More complex building units of zeolites are formed by the combination of the primary building units. The 4-corner sharing of the tetrahedra results in a microporous and low framework density. The framework density is defined as the number of T atoms per 1000  $\text{\AA}^3$  [20, 22, 23]. For understanding the structure of zeolites, it can be viewed as composite of rings which are formed by a number of tetrahedra. The name of the ring is given based on the number of tetrahedral it contains. For example, the 4-ring (4R) is consisting of 4 tetrahedra. Other tetrahedral n-rings are do exist, where n can be 4, 6, 6, 10 or 12 tetrahedra [34].

Chabazite zeolite, which exists in nature or can be synthesized in lab, owing a three dimensional network of interconnected pores with a framework density and pore dimension of 14.5 T/1000 $\text{\AA}^3$  and 3.8 x 3.8  $\text{\AA}$  (IZA), respectively. The CHA framework has been applied in different areas. CHA can be used in adsorption, ion-exchange application [71-73] and in catalysis in the conversion of methanol to olefins or in the  $\text{NH}_3$  selective catalytic reduction (SCR) of  $\text{NO}_x$  [45, 55, 74, 75]. CHA zeolite can be classified based on the Si/Al ratio into CHA with high Si/Al ratio ( $>3$ , it can be as high as 7.5 [76])

and CHA with low Si/Al ratio ( $<3$ ). The high Si/Al ratio is represented by SSZ-13 zeolite which has been firstly prepared by Zones in 1985 using N,N,N-trimethyl-1-adamantammonium (TMAda<sup>+</sup>) iodide as a template [52]. Other templates and a combination of templates and seed have been reported in the synthesis of SSZ-13 for the purpose of cost reduction [45-47, 51, 54]. Although, the CHA in which its synthesis method involves the use of templates shows excellent activity in the MTO reaction, the unusual price of templates hindered the use of CHA as a catalyst in the industry. Thus, a less expensive method for CHA synthesis is highly required.

Researchers paid a lot of efforts to make the synthesis method of CHA zeolite cheaper and thus appealing to the industry. These have been achieved by: (i) combining less expensive templates with the TMAda iodide [51], (ii) using less expensive template and seed [54], (iii) conversion of FAU zeolite with the presence of templates [49], (iv) template free conversion of FAU zeolites [41-43, 48], (v) OSDA free using seed [44] and (vi) OSDA free using fluoride route [53]. Fabricating CHA zeolite without using OSDA resulted in low Si/Al ration. The low silica zeolite decreases the activity of the CHA zeolites. However, the low silica CHA can be post-treated to reduce the alumina content. Ji et al prepared CHA zeolite by hydrothermal conversion of Y-zeolite and then post-treated using steam and acid to remove the alumina from the CHA framework [41]. In their work, they steamed the as-synthesized CHA (Si/Al = 2.4) at different temperatures to get CHA with different Si/Al ration. The dealuminated CHA showed better activity in the MTO reaction than the parent CHA.

In this work, we reported detail synthesis of cost-effective pure CHA zeolites without using any type of templates. After that, we characterized the prepared and modified

zeolites using different characterization techniques, and finally we tested the synthesized zeolite in MTO reaction.

## **3.2 Experimental**

### **3.2.1 Materials and Chemicals**

Colloidal silica TM-40 colloidal silica, 40wt.%, suspended in water (Aldrich), De-ionized water (produced in our labs labs.), ammonium fluoride, aluminum hydroxide PRS (Panreac), ammonium nitrate  $\geq 98\%$  (Sigma-Aldrich), potassium hydroxide 85% pellets (Panreac) and sodium hydroxide 85% pellets (Panreac).

### **3.2.2 Synthesis of CHA zeolites**

Pure chabazite (CHA) zeolite has been prepared hydrothermally without using any organic structure directing agent (OSDA). Our preparation method was adapted from a procedure reported elsewhere [53], but with a modified gel and wide investigations of different synthesis parameters. Aluminum hydroxide was added to an aqueous solution of potassium hydroxide under heating. Subsequently, after cooling to room temperature, ammonium fluoride and colloidal silica were added and stirred for different aging times. The final gel was hydrothermally treated in a PTFE-lined stainless steel autoclave. Thereafter, the product was separated, washed with deionized water, dried and ion-exchanged.

For preparing 40 g of the final gel, 4.21 g of potassium hydroxide was added to 17.23 g of deionized water and placed in an oil-bath at 80 °C. To the aqueous solution of potassium hydroxide, a 3 g of aluminum hydroxide was added and stirred for 30 min under heating. After cooling to room temperature, 1.07 and 14.44 g of ammonium

fluoride and colloidal silica were added, respectively. The final gel (also named as *gel# 1*) with a molar composition of 1 SiO<sub>2</sub>: 0.2 Al<sub>2</sub>O<sub>3</sub>: 0.39 K<sub>2</sub>O: 0.3 NH<sub>4</sub>F: 15 H<sub>2</sub>O was aged for x hours at room temperature, x= 6, 12, 24 and 48. Following this, the final gel was crystallized in a convection oven at 160 °C for y hours, y= 48, 72, 96 and 120. Finally the product was separated and washed with deionized water until a neutral pH around 7 was obtained. The same procedure was followed, when we prepared CHA using gel # 2, 3, 4 and 5, see **Table 4** for gels composition. For the incorporation of metals (Ni, Fe, Zn, Mg and Fe), the same procedure was followed using gel # 1 at different aging and crystallization times. The required amount (**Table 5**) of the corresponding metal was added at a stage prior to the addition of ammonium fluoride.

The as synthesized samples, which were in potassium form (K-CHA), were ion-exchanged using ammonium nitrate (NH<sub>4</sub>NO<sub>3</sub>) as a source of proton. For each gram of the sample, we used 50 mL of 2 M of NH<sub>4</sub>NO<sub>3</sub> and treated under reflux (80 °C) for 3 h. The ion-exchanged was repeated one more time with fresh solution of ammonium nitrate.

### 3.2.3 Methanol-to-olefins

The synthesized and modified catalysts with different metals were evaluated for MTO reaction using a fixed bed reactor. The reaction was conducted at 350, 400 and 450 °C using 50 mg of the prepared catalyst with a Weight Hourly Space Velocity (WHSV) of 0.95 h<sup>-1</sup>. Prior to the reaction analysis, the catalysts were calcined at 500 °C for 1 h under the flow of He. The reaction products were analyzed using an on-line Shimadzu GC-2014 chromatograph equipped with a flame ionization detector and a capillary column HP-PLOT (30 m × 0.53 mm, 6 µm film thickness).

### 3.2.4 Characterization techniques

The catalyst structure was investigated using  $^{27}\text{Al}$ , and  $^{29}\text{Si}$  Nuclear Magnetic Resonance (NMR) spectroscopy and X-ray diffraction (XRD). The XRD patterns were recorded using Rigaku Miniflex diffractometer equipped with Cu K $\alpha$  radiation ( $\lambda = 0.15406\text{ nm}$ ) at  $2\theta$  angle ranging from  $5$  to  $50^\circ$  with a scan speed of  $3^\circ$  per minute and a step size of  $0.02$ .

Ammonia temperature programmed desorption ( $\text{NH}_3$ -TPD) was conducted to investigate the acidity of the zeolites. The  $\text{NH}_3$ -TPD analysis was performed on a Chemisorb 2750 Micrometrics chemisorption analyzer over  $100\text{ mg}$  of the prepared zeolites. The sample was preheated at  $600^\circ\text{C}$  (heating rate  $30^\circ\text{Cmin}^{-1}$ ) under the flow of He ( $25\text{ mL min}^{-1}$ ) for  $30\text{ min}$ . After allowing the sample to cool to  $100^\circ\text{C}$ ,  $\text{NH}_3$  was allowed to flow over the sample with a flow rate of  $25\text{ mL min}^{-1}$  for  $30\text{ min}$ . Subsequently, He flow was reconnected for  $1\text{ h}$  to remove the weakly adsorbed  $\text{NH}_3$ . Finally, the temperature was ramped to  $800^\circ\text{C}$  at a ramping rate of  $10^\circ\text{C min}^{-1}$  and the amount desorbed of ammonia was recorded using the TCD detector on a  $0.5\text{ s}$  basis.

The elemental compositions of the samples were measured using X-ray fluorescence (XRF), while the morphology of the samples were investigated using field-emission scanning electron microscope (FE-SEM) and energy dispersive X-ray (EDX).

The surface area, pore volume and pore size distribution were measured using the physisorption of Nitrogen in ASAP 2020 (Micromeritics). Prior to analysis, the samples were heated up to  $350^\circ\text{C}$  and dwelled for  $6\text{ hours}$ . The sample temperature during the analysis was maintained at  $-196^\circ\text{C}$ . The t-plot was used to measure the volume of

micropores, surface area, and the external surface area, while the pore size distribution was estimated using Horvath–Kawazoe model method.

### 3.3 Results and discussion

#### 3.3.1 Effect of $\text{H}_2\text{O}/\text{SiO}_2$ ratio on CHA formation

**Table 4** shows different formula of the silicoaluminate gel used in this study. The first batch prepared was Run# 1, which had the same gel composition as reported in the literature [53]. However, the published procedure was not reproducible and we were unable to synthesize pure CHA from this batch even at long crystallization times, (up to 5 days). Nevertheless, by altering the water content of the first batch and fixing the crystallization time to 5 days as shown in **Table 6** (Run# 5) pure CHA zeolite was successfully formed with  $\text{H}_2\text{O}/\text{SiO}_2$  molar ratio of 15. **Figure 21** shows the XRD patterns of the CHA zeolite prepared at  $x = 15$  and the reference CHA. It is obvious that the XRD patterns of the prepared CHA at  $x = 15$  are in well agreement with the reference one; all characteristic peaks and even small peaks are matching with the reference. A further decrease in  $\text{H}_2\text{O}/\text{SiO}_2$  ratio to 10 resulted in CHA phase but with Merlinoite (MER) phase as an impurity. The XRD patterns of the CHA zeolite synthesized at different water contents are shown in **Figure 22**. From the XRD patterns, the increase in  $\text{H}_2\text{O}/\text{SiO}_2$  ratio from 15 up to 35, did not favor the formation of CHA zeolite and amorphous phases were dominating.

**Table 6. Water content and crystallization time under which CHA zeolite was formed.**

Peaks with \* symbol represents the MER phase.

**Figure 23** shows the solid-state  $^{27}\text{Al}$  magic-angle spinning (MAS) NMR spectra of the ion-exchanged samples. The typical spectrum reveals a main peak around 58 ppm attributed to tetrahedral coordination of Al species. A small peak corresponding to the octahedral coordination of Al was observed at around 0 ppm. The presence of additional structure of Al species (the octahedral) might be because of the ion-exchange [44] or by the calcination as dealumination takes place [29].

### 3.3.2 Effect of aging time on crystallization

The effect of aging time has been investigated using Gel# 1 with  $x = 15$ . We studied the effect of aging time at 4 different periods as presented in **Table 7**. The aging time had a significant influence on the crystallization time. Samples aged for longer time, required less crystallization time. For example, the minimum crystallization time for the samples aged for 6 h was between 96 and 108 h, while for those aged for 48 h require only 60 h to get pure and highly crystalline CHA zeolite. The XRD patterns of samples aged for 6 h at different crystallized times are shown in **Figure 24**, whereas the XRD patterns of samples aged for 12, 24 and 48 h with different crystallization times are shown in **Figure A1, A2, and A3** (see the appendix). An obvious picture for understanding the formation of CHA zeolites under different aging and crystallization time is depicted in **Figure 25**. The higher the aging time was, the lower the crystallization time required. All points on the line and above it represent conditions where a pure CHA zeolite can be formed, while points below the line are a combination of CHA and amorphous phase. The effect of aging time on the crystallization rate of different type of OSDA-free zeolite has been observed elsewhere [77-80]. M. Ahmed et al. varied the aging time from 3 to 24 h at room temperature over EU-1 zeolite. They found that the crystallinity was increased with the increase of aging time from 3 to 12 h. A further increase in aging (up to 24 h) negatively affected the crystallinity and purity of EU-1 zeolite. In contrast, we found a continuous increase in the crystallization rate with the increase of aging time. This could be because of the type of silica source (colloidal silica Ludox TM 40%) used in the synthesis of CHA zeolite. The rule of various silica sources in studying the effect of aging time on the crystallization rate has been studied by Qinghua and his coworkers on

TPA-silicalite-1 [81]. They found that the colloidal silica Ludox TM required a longer aging time to have similar effect as other sources of silica.

**Figure 24.** XRD patterns of samples prepared from Gel # 1 with  $x(\text{H}_2\text{O}/\text{SiO}_2) = 15$  at 6 h of aging and different crystallization times.

**Figure 25. Formation of CHA zeolite at different aging and crystallization times.**

### 3.3.3 Effect of aging time on morphology

Aging time did not only lower the crystallization time but it also influenced the morphology (particles' shape and size) of the prepared CHA zeolites. Samples prepared at lower aging time had different particle shape and size than samples prepared at higher aging time. Generally, the particles are small cuboids, which are agglomerated to form large particles that are similar to a swollen-disk like shape. **Figure 26** shows FE-SEM images of CHA zeolite which was aged for 6, 24 and 48 h with a corresponding minimum crystallization time. For the aging time of 6 h and crystallization time of 108 h, the swollen disk-like particles' shape seems to be interconnected to form a flower-like shape. The size of these interconnected particles ranged between 15 to 20  $\mu\text{m}$ , while the small cuboids which are the components of the larger particles had a size of 1.2-2  $\mu\text{m}$ . The increase in aging time affected both the swollen disk-like shape and the small

cuboids. The flower-like shape was not anymore interconnected and appeared to be more dispersed with a size ranging between 10 and 18  $\mu\text{m}$  when the aging time was 24 h. Moreover, the size of the small cuboids was as small as 0.8  $\mu\text{m}$ , even at 24 h aging time. A more increase in aging time up to 48 h caused a desertion to the swollen disk-like shape as they become more spread and irregular in shape. Additionally, the small cuboids size decreased to 400 nm. Alfaro et al [77] found that the particle size was decreasing with the increase of aging time of LTA zeolite. Other studies [79, 80] in the literature are in-agreement with our finding.

**Figure 26. FE-SEM images at different magnifications of CHA zeolites prepared at aging time of 6 h (a, b and c), 24 h (d, e and f) and 48 h (g, h and i) at a minimum time of crystallization.**

### 3.3.4 Effect of varying Al<sub>2</sub>O<sub>3</sub>- NH<sub>4</sub>F-K<sub>2</sub>O / SiO<sub>2</sub> ratios

**Table 8** shows different gel compositions (Gel# 2, 3 & 4) of the precursor solution. The Si/Al ratio has been varied in the gel composition in order to have CHA zeolites with different Si/Al ratio. However, an increase in the Si/Al ratio either by decreasing the source of aluminum or by increasing the source of silica resulted in MER as a competitive phase or an amorphous phase as shown in **Figure 27**. Similarly, altering the concentration of K<sub>2</sub>O and NH<sub>4</sub> did not favor the formation of CHA zeolite. The introduction of small concentration of Na<sub>2</sub>O beside K<sub>2</sub>O (Gel# 5, Run# 25 & 26, **Table 8**) for the purpose of varying alkaline metals suppressed the formation of CHA zeolite and favor the growth of MER phase.

**Table 8. Effect of altering fluoride and aluminum content on the formation of CHA zeolite**

### 3.3.5 Surface area and pore volume distribution

Ion-exchange of the as-synthesized zeolite was carried out using 2 M of ammonium nitrate at 75 °C for 3 h. **Table 9** shows the physical properties of the prepared CHA samples before and after ion-exchange. The as-synthesized material in potassium form (K-CHA) had a small surface area, while the ion-exchanged sample in H-form (H-CHA) showed an excellent enhancement in the surface area and pore volume. The parent sample (K-CHA), initially, had a BET surface area of 0.962 m<sup>2</sup>/g and total pore volume of 0.0032 cm<sup>3</sup>/g. After ion-exchange, the BET surface area and pore volume increased to 485 m<sup>2</sup>/g and 0.217 cm<sup>3</sup>/g, respectively. The poor adsorption of the parent sample is due

to the large size of the potassium cation ( $K^+$ ) which might block the pore of the CHA framework [82]. A poor adsorption of CHA in K-form and an enhancement in adsorption when the CHA zeolite was ion-exchanged with  $Ca^+$  and  $Na^+$  has been observed elsewhere [43, 82, 83] and summarized in **Table 9**. Nedyalcova and his coworkers [43] found that CHA in potassium form had a surface area of ca.  $7.9 \text{ m}^2/\text{g}$  and then enhanced to ca.  $396 \text{ m}^2/\text{g}$  after ion exchange. Similarly, Shang et. al [83] reported a micropore volume of  $0.0008 \text{ cm}^3/\text{g}$  when the CHA was in potassium form.

**Figure 28** presenting the  $N_2$  adsorption/desorption isotherm of K-CHA and H-CHA zeolites. The isotherm belongs to type I and IV isotherm, which is the common isotherm type of CHA zeolite [84, 85]. The pore width of H-CHA zeolite was calculated using the Horvath–Kawazoe model with a main peak at ca.  $5.1 \text{ \AA}$ , as shown in **Figure 29**.

**Table 9. Surface area, pore volume and Si/Al ratio of the CHA samples.**

Sample	Surface Area ( $\text{m}^2/\text{g}$ )				Pore volume ( $\text{cm}^3/\text{g}$ )			Si/Al <sup>a</sup>	Ref.

Figure 29. Micropores of synthesized and modified CHA zeolite samples using Horvath-Kawazoe model

The  $\text{NH}_3$ -TPD profile of the as synthesized CHA zeolite before and after ion-exchange is depicted in **Figure 30**. The sample in K-form had only a single small peak at  $T \sim 175^\circ\text{C}$  attributed to weak acid sites. However, after ion-exchange (H-CHA), the TPD profile of ammonia showed two peaks at  $T = 195^\circ\text{C}$  and  $475^\circ\text{C}$  corresponding to weak and strong acid sites, respectively.

**Figure 30.**  $\text{NH}_3$ -TPD profiles of the as-prepared CHA zeolite in K-Form (K-CHA) and after ion-exchanged with 2 M of ammonium nitrate (H-CHA).

### 3.3.6 CHA activity in MTO reaction

The activity of the synthesized CHA zeolites was evaluated in the MTO reaction at three temperatures (350, 400 and 450°C) with a WHSV of 0.95 h<sup>-1</sup> in a fixed bed reactor. The selectivity and conversion of the CHA zeolites at the three temperatures are shown in **Figure 31** and **32**, respectively. From **Figure 31**, it is obvious that Al-rich CHA at lower reaction temperature (350°C) was more stable than at 400 and 450 °C. At 350°C, the conversion was maintained ca. 100% for more than 180 min, while at 400 and 450 °C the conversion decreased below 100% at TOS ca. 60 min. The increase in deactivation rate of CHA, which contains a high percent of alumina as a function of temperature was reported also by Bleken, et. al [58]. Bleken and his coworkers studied the effect of temperatures on SAPO-34 and SSZ-13. SSZ-13 is more acidic and is similar in acidity to our Al-rich CHA zeolite. Thus our results are in agreement with the behavior of SSZ-13 as shown in **Figure 33**.

**Figure 31. . Conversion of methanol over Al-rich CHA as a function of temperatures.**

Figure 32. Selectivity to olefins as a function of temperatures.

Figure 33. Effect of temperature on catalyst stability [58].

The selectivity to olefins as a function of temperatures is shown in **Figure 32**. At 350°C, the selectivity to light olefins was increased with TOS before the catalyst deactivated. At the beginning of the reaction, total olefins selectivity was ca. 62% and increased up to 93.8% at TOS of 180 min. In contrast, at higher temperatures (400 and 450°C), the selectivity to light olefins was higher at the initial of the reaction as presented in **Table 10**. The increase in selectivity to olefins with the increase of TOS and temperature was reported in the literature [86, 87]. The low selectivity to olefins at the initial of the reaction might be because part of olefins is consumed to form different hydrocarbon species. Additionally, propylene is more reactive at lower temperatures and has a tendency to form oligomers. The tendency of oligomers formation decreases with the increase of temperature as they crack to form more ethylene [86].

**Table 10. Products distribution as a function of temperatures over Al-rich CHA.**

TOS	350°C				400°C			450°C		
	10	60	120	180	10	60	120	10	60	120

The selectivity comparison of Al-rich CHA to the commercial ZSM-5 and SSZ-13 at the same reaction conditions is depicted in **Figure 33**. At TOS 60 min, SSZ-13 showed the highest selectivity, however at higher TOS (120 and 180 min) our Al-rich CHA was the most selective catalyst. In agreement with literature, selectivity to olefins, particularly ethylene, was decreased with the increase of TOS [58, 86]. This decrease in the selectivity was explained by the pore blockage caused by carbon deposition which hinders the diffusion of propylene [58]. The pore blockage is more obvious when the reaction temperature was 450 °C as a result of coke formation.

**Figure 34.** Comparison of olefins selectivity of Al-rich CHA commercial ZSM-5 and SSZ-13

### 3.3.7 Incorporation of metals

Different metals have been incorporated to the framework of CHA zeolites as indicated in **Table 5**. Only selected samples have been evaluated in the MTO reaction. Figure 35 shows the conversion of methanol of MeCHA zeolites. All MeCHA catalysts showed a 100% conversion of methanol. However, only BCHA and NiCHA maintained 100% conversion of methanol after 1 h of TOS, while the other MeCHA zeolites deactivated after 10 min TOS.

Figure 35 . Conversion of methanol over MeCHA zeolites; reaction temperature 350 °C, WHSV =0.95 h<sup>-1</sup>

**Figure 36. Total olefins selectivity of MeCHA zeolites compared to the parent CHA zeolite.**

**Figure 36** shows the total olefins selectivity of MeCHA zeolites after 10 and 60 min of the beginning of the reaction. After 10 min TOS, the CHA zeolites incorporated with magnesium ( $\text{Mg/SiO}_2 = 0.02$ ) and zinc ( $\text{Zn/SiO}_2 = 0.02$ ) were the most selective catalysts. The total olefins selectivity for ZnCHA was ca 82%, while for MgCHA it was ca. 78%. The enhancement in the total olefins selectivity for ZnCHA and MgCHA compared to parent CHA (H-CHA) was ca. 20 and 16 %, respectively. However, these two catalysts deactivated rapidly and showed no activity when TOS was 60 min. The CHA incorporated with nickel ( $\text{Ni/SiO}_2 = 0.02$ ) and boron at different concentrations ( $\text{B/SiO}_2 = 0.05$  and  $\text{B/SiO}_2 = 0.1$ ) showed comparable selectivity to olefins after 60 min of the reaction. Both NiCHA and BCHA ( $\text{B/SiO}_2 = 0.1$ ) maintained a total selectivity ca. 80% which is lower than the parent CHA by ca. 6%. Thus, the metal incorporation to the framework of CHA zeolite by in-situ method enhanced the activity of the catalyst at the beginning of reaction. After 60 min TOS, all MeCHA zeolites were deactivated and showed no activity in the MTO reaction.

### 3.3.8 Conclusions

Cost-effective Al-rich CHA zeolite was successfully synthesized without using templates. The CHA zeolite was synthesized under different experimental conditions than what was reported in the literature. The Si/Al ratios of the gel had a crucial role in the formation of pure CHA zeolite. A slight increase in Si/Al ratio (Si/Al=3.3) caused formation of impurities of other phase (MER). Higher H<sub>2</sub>O/SiO<sub>2</sub> ratio affected the crystallinity of CHA zeolite, in which lower H<sub>2</sub>O/SiO<sub>2</sub> ratio favored the formation of MER phase. The aging time influenced both the particles' shape and size, and the rate of crystallization. At longer aging time, smaller CHA particles were synthesized with shorter crystallization times. The synthesized CHA zeolite in H-form (H-CHA) showed a higher surface area and pore volume than the K-form (K-CHA). The reaction evaluation of H-CHA showed that the Al-rich CHA zeolite was very selective to olefins. The deactivation rate and initial selectivity to olefins were linked to the reaction temperature. The selectivity of the Al-rich CHA zeolite in the MTO reaction was comparable to the commercial ZSM-5 and SSZ-13 catalysts. Ni, Mg, Fe, B and Zn were successfully incorporated to the CHA framework by in-situ method. The incorporation of metals affected negatively the stability of the catalyst. However, the metal incorporation had a significant enhancement to the total olefins selectivity at the beginning of the reaction. Thus MeCHA zeolites are promising MTO catalysts to be used in a fluidized bed reactor.

## **CHAPTER 4**

# **Microwave-Assisted Hydrothermal Synthesis of Al-rich CHA Zeolite from Amorphous Aluminosilicate Gel in the Presence of a Seed**

### **Abstract**

Cost-effective aluminum (Al) rich CHA zeolite was synthesized by seed-assisted hydrothermal synthesis under microwave irradiation to shorten the crystallization time. Al-rich CHA zeolite was successfully synthesized within 6 h. The Al CHA was synthesized under different stirring rates and evaluated for the methanol-to-olefins reaction at three different temperatures in a fixed bed reactor. After the successful synthesis of the SDA-Free CHA zeolite, boron was incorporated by in-situ synthesis. The XRD pattern revealed that the synthesized CHA was crystalline. The performance evaluation revealed that reaction temperature and TOS affected both the catalyst's stability and selectivity to light olefins. At lower temperature (350 °C), the Al-rich CHA was more stable and less selective to light olefins at the beginning of the reaction. The selectivity was increased from 41.8% at TOS of 10 min up to 85.0% at TOS of 120 min. In contrast, the selectivity of olefins at TOS of 10 min was 55.0 and ca. 79.6% when the reaction temperatures were 400 °C and 450 °C, respectively. Incorporation of boron only enhanced the olefins selectivity at the initial stages of the reaction. At 350 °C, the total olefins selectivity was increased from 41.8% for parent CHA to 71.5% for CHA with Si/B=13.

## 4.1 Introduction

Zeolites are crystalline porous materials with tunable and distinct properties. They are mainly composed of aluminum, silicon, oxygen and phosphorous in some frameworks. There are more than 220 zeolites frameworks recorded in the international zeolite association (IZA). Each framework has its own property such as pore diameter, crystal habit, pore dimension, framework density and compositions, to mention but a few. Due to these exceptional properties, they have been applied in wide range of applications. For example, zeolites are be used in separation, adsorption, ion-exchange and purifications [88-90]. Zeolites properties such as high surface area, well defined channels and cavities, controlled adsorption capacity, availability of active sites, shape selective and hydrothermal stability open plethora applications in hydrocarbon catalysis [32, 89, 90]. One of the most challenging reactions is the conversion of methanol-to- olefins (MTO), which is the focus of this study. Many factors are still explored to optimize MTO process, including development of better effective catalyst.

There are different types of zeolites frameworks used in the MTO reaction [7, 91-95]; however, zeolites with MFI and CHA topology have been proved to have superior activities. These two frameworks exhibited different selectivities to light olefins and slower deactivation rate. The selectivity is governed by the pore and cage size, while the deactivation rate is affected by the catalyst's acidity [6, 40, 94]. Thus, ZSM-5, which has a medium pore opening and can be synthesized with varying amount of acid sites, is an outstanding catalyst in the MTO reaction in term of stability, but it produces a wide range of products. In contrast, SAPO-34 with small pore opening and contains on large amount

of acid sites is the most selective catalysts to light olefins, but it suffers from severe deactivation.

The synthesis method of CHA zeolites involves the use of the expensive template N,N,N-trimethyl-1-adamantammonium iodide as structure directing agent (SDA) [52]. Other strategies for CHA synthesis in which a combination of the expensive template with cheaper SDAs have been reported in the literature [54]. Bull and his coworkers were patented for the conversion of a pre-synthesized zeolite (FAU) to CHA without using templates [96]. However, the synthesis of CHA zeolite from the conversion of FAU zeolites produces CHA with low silica content ( $\text{Si/Al} = 2\text{-}2.5$ ) that has a negative effect in the MTO process. Imai et al [44] reported a direct SDA-Free synthesis of CHA zeolite from amorphous silicoaluminate gel in the presence of seed. In this study, we focused on the production of cost-effective CHA zeolite utilizing the microwave-assisted hydrothermal synthesis (MAHyS) from the amorphous of silicoaluminate gel.

In this study, we focused on the production of a cost-effective Al-rich CHA zeolite utilizing the microwave-assisted hydrothermal synthesis (MAHyS). Microwave is a powerful platform with a wide range of applications. Regardless of its massive use in food coking, the first use of microwave in laboratory was in drying and moisture analysis [97]. Then, the microwave technology has been utilized in the field of material synthesis of inorganic chemistry in the late 1970s and in organic synthesis in the 1980s [98]. The first report for chemical synthesis (organic synthesis) has been published in 1986 by Gedye et al. [99]. After 1990, the number of publications using microwave technology have been noticeably increased because the commercialization of the technology. Regarding the synthesis of zeolite using microwave, Mobile Oil Corporation in 1988

patented on the zeolite synthesis using microwave [100], while the first article concerning the synthesis of NaA and ZSM-5 zeolites was published by Arafat et al in 1993 [101]. Since that time, the number of articles reported on the synthesis of zeolites using microwave heat was continuously increased [102-108]. The main benefits of the microwave synthesis are shorter synthesis time, reduced particle size and uniform particle shapes. Rapid synthesis (MAHyS) of Al-rich CHA has been established within this study, even though the Al content supposed to slower the crystallization growth [109].

## **4.2 Experimental**

### **4.2.1 Synthesis of Al-rich CHA**

Pure chabazite (CHA) zeolite was successfully synthesized under microwave radiations. The synthesized CHA was prepared in the presence of a CHA Seed from amorphous silicoaluminate gel without any addition of templates. The compositions of the amorphous gel was adopted from the literature [44]. Our synthesis procedure includes the addition of aluminium iso-propoxide to an alkaline solution of sodium and potassium hydroxide. Then, fumed silica and a required amount of seeds were added. After that, the final gel was crystallized in a microwave lab station (400 W, MicroSYNTH, Milestone, Italy) at 170 °C for certain hours. In a typical preparation, 0.5 g and 0.23 g of sodium and potassium hydroxide, respectively, were dissolved in 37.6 g of deionized water. To this alkaline solution, 0.43 g of aluminum iso-propoxide was added and stirred at 450 rpm for about 1 h. Prior to the addition of 0.25 g of seeds, 1.25 g of fumed silica was added and stirred for 30 min. The final gel was crystallized at 170 °C for  $x$  hours, ( $x= 5, 6, 6.5, 7$  and 8 hours) at a stirring rate of 50 rpm. After optimizing the crystallization time at 50 rpm, we synthesized CHA zeolite at higher stirring rate (400 rpm). Then, we incorporated

boron at 400 rpm for different crystallization times as shown in **Table 14**. The required amount of boron was introduced after the addition of aluminum and then the experimental procedure was the same as if the sample was free of boron. Thereafter, the product was separated by centrifugation, washed with deionized water, dried and ion-exchanged.

The ion-exchanged was performed using ammonium nitrate ( $\text{NH}_4\text{NO}_3$ ) as a source of proton. For each gram of the sample, we used 50 mL of 2 M of  $\text{NH}_4\text{NO}_3$  and then the solution was heated using microwave at 85 °C for 25 min, at a heating rate 17 °C per minute. The ion-exchanged was repeated one more time with a fresh solution of ammonium nitrate. Finally, the samples were calcined to obtain H-CHA at 500 °C for 4 h, at heating rate of 5 °C/ min.

#### 4.2.2 Characterization techniques

##### *Structure and morphology analysis*

The crystallinity of the synthesized samples was explored using X-ray diffraction (XRD) machine, Rigaku Miniflex diffractometer equipped with Cu  $K\alpha$  radiation ( $\lambda = 0.15406$  nm). The XRD patterns were recorded in  $2\theta$  angle ranging from 5 to 50° with a scan speed of 3° per minute and step size of 0.02. The crystallinity (**Table 14**) was calculated by the relative intensities of mean peaks at  $2\theta \sim 9.5, 20.5, 30.7$  and  $31.2^\circ$  as follow:

$$\text{Crystallinity} = \frac{\Sigma(\text{mean peaks of } x \text{ sample})}{\Sigma(\text{mean peaks of pure CAH sample})}, \text{ where the pure was Run\# 7.}$$

The  $^{27}\text{Al}$ , and  $^{29}\text{Si}$  solid state Nuclear Magnetic Resonance (NMR) was used to study the coordination of the aluminum and silicon in the CHA framework. The elemental compositions of the samples were measured using X-ray fluorescence (XRF) and energy

dispersive X-ray (EDX), while the morphology of the samples was investigated using the field-emission scanning electron microscope (FE-SEM).

### ***Acidity analysis***

We conducted the ammonia temperature programmed desorption (NH<sub>3</sub>-TPD) to investigate the acidity of the zeolites. Typically, a 100 mg of H-CHA zeolite was used for the acidity measurement in a Chemisorb 2750 Micrometrics Chemisorption analyzer. Firstly, we preheated the sample at 600 °C (heating rate 30 °C.min<sup>-1</sup>) for 30 min under the flow of helium (25 mL. min<sup>-1</sup>). Then, the samples were cooled to 100 °C and allow ammonia to flow over the samples for 30 min at rate of 25 mL. min<sup>-1</sup>. To remove the weakly adsorbed ammonia, the samples were flushed with helium at the same previous conditions for 60 min. Finally, we heated the sample up to 650 °C at heating rate of 10 °C. min<sup>-1</sup> and the amount desorbed of ammonia was collected using a TCD detector.

### ***Surface area and pore volume distribution***

The N<sub>2</sub> adsorption /desorption isotherm was conducted to study the textural properties of the synthesized catalysts. The samples firstly were degassed at 300°C for 12 h and then the analysis was performed in a liquid nitrogen bath at -195.86°C. The surface and pores volume were calculated using the BET method, while the micropores distribution and micropore area were calculated using the Horváth–Kawazoe and the t-plot methods, respectively.

### 4.2.3 Catalytic Evaluation

The activities of the synthesized and modified catalysts with different concentrations of boron were evaluated in a fixed bed reactor with a WHSV of  $0.94\text{ h}^{-1}$  over 50 mg of the catalyst. Prior to the analysis, the samples firstly were calcined for 1 h and then evaluated at three different temperatures; 350, 400 and 450 °C. An on-line Shimadzu GC-2014 chromatograph equipped with a flame ionization detector and a capillary column HP-PLOT (30 m  $\times$  0.53 mm, 6  $\mu\text{m}$  film thickness) was used to quantify the products distribution.

### 4.3 Results and Discussion

**Table 11. Experimental conditions for microwave-assisted hydrothermal synthesis (MAHyS) of CHA zeolite.**

Run#	Crystallization Time (h)	T (°C)	Seed	Stirring (rpm)	Phase	Si/Al <sup>a</sup>	Si/B <sup>a</sup>	Relative Crystallinity
1	5	170	-	50	MER	10	-	-
2	6	170	-	50	MER	10	-	-
3	8	170	-	50	MER	10	-	-
4	5	170	CHA	50	CHA (Am.)	10	-	-
5	6	170	CHA	50	CHA (Am.)	10	-	-

<sup>a</sup>: ratios of the amorphous silicoaluminate gel.

\*: the CHA phase is containing on a tiny impurities, very small peak appeared at  $2\Theta = 12.4^\circ$

#### 4.3.1 Seed-Free Crystallization

To synthesize pure Al-rich CHA from amorphous aluminosilicate gel, firstly, we investigated the synthesis without using a CHA seed for three different crystallization periods; 5, 6 and 8 h. As shown in **Figure 37**, CHA zeolite was not obtained in the absence of a CHA seed. The seed-free synthesis only favors the formation of another phase of zeolite, namely MER. This finding is in well agreement with previously reported crystallization work using conventional heating [44].

**Figure 37. XRD patterns of CHA samples crystallized by MAHyS without using seed at different crystallization times.**

#### 4.3.2 Seed-assisted Crystallization

Once the CHA seed has been added to the gel, 20 wt.% of silica, CHA zeolites was formed at different crystallization times. **Figure 38** shows the XRD patterns of the as-synthesized CHA zeolites using microwave heating. It is obvious from the XRD patterns that crystallization time has a great influence on the formation of CHA zeolite. Higher

crystallinity and pure CHA zeolite was achieved at a crystallization time of 6.5 h and a stirring rate of 50 rpm. All peaks of the pure CHA zeolite were in well agreement with the CHA reference. Shorter crystallization times, 5 and 6 h, resulted in a combination of CHA and amorphous phase. When the crystallization time was increased to 7 h, crystallinity was maintained but a minor peak of an impurity (MER) phase appeared at  $2\theta = 12.4^\circ$ . In line with our previously reports for different zeolite frameworks, we successfully synthesized CHA with significantly shorter time (6 h) than MOR [110] and MTT [105] zeolite under microwave radiation. However, the increase in crystallization time stimulated the appearance of impurity phase.

**Figure 38.** Synthesis of CHA zeolite by MAHyS in the presence of seed (20 wt. % of silica) at different crystallization times with stirring rate of 50 rpm.

### 4.3.3 Effect of Stirring

The preparation of Al-CHA zeolite using conventional heating, was carried out at slow stirring rate, 20 rpm, using a tumbling oven. Therefore, in our study, we initiated the synthesis at very slow stirring rate and then we increased the speed of the stirring rate to investigate its effect on crystal growth, morphology and catalyst activity. The initial stirring rate was 50 rpm. At this stirring rate, pure CHA zeolite was formed at crystallization time of 6.5 h and 170 °C (Run# 7). At the same conditions, but with higher stirring rate (400 rpm), CHA zeolite was formed but with an additional small peak of MER phase at  $2\theta = 12.4^\circ$  as shown in **Figure 39**. The additional peak is attributed to a MER framework. However, when crystallization time was decreased to 6 h, still with 400 rpm stirring rate, we were able to get pure CHA zeolite. This implies that stirring rate influences the rate of crystallization. The higher stirring rate was the lower the required crystallization time. The effect of stirring rate on crystallization has been noticed elsewhere [105, 111, 112]. It has been reasoned that higher stirring rate would prevent the mass-transfer limitations. Thus, the lower mass-transfer limitation would give rise to higher nucleation and crystallization rate<sup>30</sup>.

**Figure 39. XRD patterns of the synthesized CHA by MAHyS at different crystallization times and different stirring speeds.**

**Figure 40** shows the  $^{27}\text{Al}$ , and  $^{29}\text{Si}$  solid state NMR spectra for the samples synthesized at different stirring rates. The  $^{27}\text{Al}$  NMR spectra show a sharp peak at around 58 ppm corresponding to tetrahedral coordination, and a tiny resonance at around 0 ppm attributed to the octahedral environment. The  $^{29}\text{Si}$  resonance spectra (for both samples synthesized at 50 and 400 rpm) show two large peaks located at ca. -109 ppm and -105 ppm, corresponding to Si(0Al) and Si(1Al) coordination, respectively. Another two minor  $^{29}\text{Si}$  resonance spectra centered at ca. -99 ppm and -93 ppm were attributed to Si(2Al) and Si(3Al) coordination, respectively.

**Figure 40.** The  $^{27}\text{Al}$  and  $^{29}\text{Si}$  MAS NMR spectra of the CHA zeolites by MAHyS synthesized at different stirring rates

#### 4.3.4 Effect of boron incorporation on crystallization

We studied in-situ incorporation of boron at different concentrations. Firstly, we attempted to incorporate boron with a Si/B molar ratio of 50 over Run# 9, crystallization time 6 h and at a stirring rate of 400 rpm. However, the addition of boron decreased the rate of crystallization, and we obtained a combination of amorphous and CHA phases after the addition of boron, as shown in **Figure 41**. The crystallinity was 90% for CHA free of boron and then decreased to 40% after the boron incorporation at the same experimental conditions. Thus, to obtain a well crystalline and pure CHA phase, we had to optimize both the crystallization time and stirring rate. Therefore, crystallization time was increased up to 7 h, while the stirring rate was maintained at 400 rpm, but this resulted in the appearance of a small peak at  $2\theta = 12.4^\circ$  (Run# 12). With the same stirring

speed, we have increased the boron concentration so that the Si/B ratios were 20 and 13. The increase in Si/B ratio from 20 to 13 suppressed the peak appeared at  $2\Theta = 12.4^\circ$  as shown in **Figure 41**. **Table 12** presents the elemental compositions (in wt. %) of the samples synthesized before and after boron incorporation. The boron addition influenced the Si/Al ratio; the highest Si/Al ratio was 4.54 corresponding to the highest amount of boron.

**Figure 41.** XRD patterns of the synthesized CHA zeolite by MAHyS at different concentrations of boron

**Table 12. Elemental compositions of as-synthesized CHA zeolites prepared using microwave (MAHyS) heating.**

Sample	Al	Si	B	Si/Al	Si/B	Si/B <sup>a</sup>
Run#7	7.90	29.59	-	3.75	-	-
Run#13	7.77	30.51	8.4	3.93	3.85	1.08
Run#14	6.05	27.48	12.98	4.54	2.13	2.14

#### 4.3.5 Physical properties and morphology of Al-rich CHA zeolite

The amount and strength of acidic sites of the synthesized samples were evaluated using NH<sub>3</sub>-TPD. The TPD analysis has been conducted for selected samples as presented in **Table 13** and shown in **Figure 42**. All the analyzed samples had two peaks that usually appeared in the NH<sub>3</sub>-TPD profile, the l-peak and h-peak [113], which were observed at a temperature of 120-400 and 400-650 °C, respectively. The peaks appeared in the NH<sub>3</sub>-TPD profile expressed different amounts of acid type. Samples synthesized without the incorporation of boron or with lower Si/B ratio had similar amount of acid; the samples synthesized from Run # 7, 9 and 13 had similar densities of acid sites as shown in **Table 13**. **Figure 43** shows the typical N<sub>2</sub> adsorption-desorption of Al-rich CHA with minor presence of mesopores (Type IV). **Table 13** presents the comparison of the physical properties of CHA zeolites synthesized using conventional and microwave heating. The presented BET results reveal that the microporous CHA zeolite synthesized using

microwave heating possess high surface area (up to 578 m<sup>2</sup>/g) and the presence of mesopores (ca. 25%). CHA synthesized using microwave heating had relatively fewer amounts of acid sites, which was reflected later on the catalyst stability in the MTO reaction as explained in Section 4.3.6. The Al-rich CHA zeolite synthesized at 50 and 400 rpm exhibited almost similar pore volume and sizes, which were calculated using Horváth–Kawazoe method as depicted in **Figure 44**. This shows that mesoporisoty is not highly affected by the stirring speed.

**Figure 42.** NH<sub>3</sub>-TPD of the CHA samples synthesized under microwave irradiation with different stirring rates and different concentrations of boron.

**Table 13. Physical properties of the CHA zeolites prepared microwave (MAHyS) and conventional heating.**

Sample	Surface Area [m <sup>2</sup> /g]			Pore Volume [cm <sup>3</sup> /g]				Acid amount [mmol g <sup>-1</sup> ]		
	$S_{\text{BET}}$			$S_{\text{L}}$	$V_{\text{micro}}$	$V_{\text{meso}}$	$V_{\text{tot}}$	weak	strong	Total
	$S_{\text{ext}}$	$S_{\text{micro}}$	$S_{\text{tot}}$							
T-CHA	66.8	512	578	704	0.217	0.077	0.294	-	-	0.90
Run# 7	42.5	535	577	698	0.227	0.070	0.297	0.55	0.30	0.85
Run# 9	41.1	505	546	660	0.214	0.057	0.271	0.46	0.30	0.76
Run# 13	-	-	-	-	-	-	-	0.55	0.43	0.98
Run# 14	-	-	-	-	-	-	-	0.19	0.35	0.54

**Figure 44. Cumulative pore volume distribution using Horvath-Kawazoe plot.**

The SEM images of the samples shown in **Figure 45** revealed that the obtained CHA particles are in a nano size range of around 150 nm. These small particles are agglomerated in a very ordered way to form a sheet, which is similar in shape to corn flakes sheets. These corn flakes like shapes have a thickness ranging between ~ 130 and 160 nm.

**Figure 45. FE-SEM images of the CHA zeolites synthesized by MAHyS in the presence of seed at different crystallization times and stirring rates; Run# 7 (left side) and Run# 9 (right side).**

### 4.3.6 Catalyst Evaluation

The catalytic performance of the synthesized samples has been evaluated in methanol-to-olefins reaction using a fixed bed reactor. Firstly, we studied the effect of reaction temperature on catalysts activity over Run# 7 of Chapter 4. **Figure 46** shows the conversion and selectivities to light olefins at three different temperatures; 350, 400 and 450 °C. At all reaction temperatures, the conversion maintained 100% for the first 60 min with different selectivities to light olefins. At 120 min time on stream (TOS), the sample which was tested at 400 °C started to deactivate with a conversion decreased to around 80%, while for the samples tested at 350 and 450 °C the conversion was maintained above 92%. After 150 min, all catalysts suffered from severe deactivation. In term of stability, CHA sample tested at 350 °C is the most stable than at 400 and 450 °C. This finding is in agreement with our previous finding in chapter 3 and also with literature [58], in which zeolites with high amount of acid sites deactivate faster at higher temperatures.

**Table 14** shows the products distribution of the MTO reaction over CHA zeolite catalyst evaluated at the three different temperatures. Obviously, both the reaction temperature and TOS had an influence on the selectivity toward light olefins. At the initial stage of the reaction (TOS = 10 min), the selectivity was maximum ca.80% when the reaction temperature was 450 °C, and minimum (ca. 42%) at 350 °C. Then, with the increase of TOS, the selectivity of olefins (especially ethylene) was increased at all reaction temperatures. In contrast to ethylene, the propylene selectivity was increased slightly at temperatures of 350 and 400 °C. However, when the temperature was 450 °C, the selectivity to propylene decreased with the increase of TOS. The increase in ethylene

selectivity at higher temperature was due to coke formation, which blocked the pore and disturbed the diffusion of propylene [58]. Another reason is the reactivity of propylene, which undergoes oligomerization reaction to form large oligomers, which cannot diffuse out through the CHA pore [86]. These large oligomers later crack to form ethylene [86].

**Figure 46 . Conversion of methanol and selectivity to total light olefins over CHA zeolite evaluated at different temperatures.**

**Table 14. Product distribution of CHA zeolite (Run# 7) at different temperatures.**

Temperature (°C)	350			400			450		
TOS (min)	10	60	120	10	60	120	10	60	120
Conv. (%)	100	100	98.2	99.9	100	80.8	100	100	92.5
Propene (%)	14.53	32.93	30.34	20.05	30.15	17.4	23.13	21.99	15.01

MTO reaction was also performed over the CHA zeolite synthesized at 400 rpm to investigate the effect of stirring on the catalyst activity. The performance of the catalyst at higher stirring rate was slightly better in term of selectivity to light olefins than the one at lower stirring rate, as shown in **Figure 47**. For example, the maximum total olefins selectivity was 92.26 over the 400 rpm catalyst, while over the 50 rpm catalyst, the selectivity was 84.96, as shown in **Table 15**. This relative enhancement in the catalyst activity is due to the slightly lower acidity of the sample prepared at 400 rpm, as presented in **Table 13** and **Figure 42**.

**Figure 47. Methanol conversion and selectivity to total light olefins synthesized at different stirring rates; H-CHA-6.5h-50rpm (Run# 7) and H-CHA-6h-400rpm (Run# 9)**

**Table 16** shows a comparison of products distribution between the CHA synthesized under microwave radiation and the CHA synthesized using conventional heating [44] at the same reaction conditions and gel composition. Obviously, our Al-rich CHA zeolite showed a higher stability and, relatively, higher selectivity to light olefins. The higher stability of our catalyst might be because of the slightly lower amount of acid sites as presented in **Table 13**. The boron incorporation had a negligible effect on the selectivity and catalyst stability. At lower boron incorporation ( $\text{Si/B} = 20$ ), as shown in **Table 15** and **Figure 48**, methanol conversion and total olefins selectivity were decreased from 100 to 96% and from 92.3 to 80.9%, respectively as compared to the parent CHA zeolite (Run# 9). Although a higher content of boron incorporation decreased the stability of the catalyst, the sample showed higher selectivity to olefins at the initial of the reaction (TOS= 10 min) as compared to the parent CHA catalyst. Qingium Zhu et. al[114] synthesized a borosilicate CHA zeolite which was evaluated in the MTO reaction. In agreement with our finding, the incorporation of boron of the borosilicate CHA reduced the catalyst stability and activity toward light olefins as shown in **Figure 49**.

**Figure 48.** Methanol conversion and selectivity to total light olefins over samples synthesized at different concentrations of boron; Si/B =20 (Run# 13) and Si/B =13 (Run#14).

#### 4.3.7 Conclusions

Up to our knowledge, for the first time, microwave irradiation has been utilized to synthesize an OSDA-Free Al rich CHA zeolite. Microwave heating decreased the crystallization time from 24 to 6 h. The synthesized CHA zeolites samples showed excellent activity in the MTO reaction. The selectivity to lower olefins was linked to the higher reaction temperatures and TOS. At higher temperature, 450 °C, the synthesized CHA zeolite was more selective to light olefins especially at the beginning of the reaction. Similarly, as TOS increased, the selectivity to light olefins was increased as well. This increase in selectivity with TOS was not significant at a reaction temperature of 450 °C. The highest boron incorporated CHA catalyst increased only the amount of

olefins produced at the beginning of the reaction, while the low content boron incorporation did not contribute significantly to the activity of CHA catalyst.

## CHAPTER 5

### Conclusions and Recommendations

This chapter will restate the conclusions of the two approach used in this study, and will give recommendations.

For the first approach, Cost-effective Al-rich CHA zeolite was successfully synthesized without using templates. The CHA zeolite was formed under different experimental conditions than what was reported in the literature. The Si/Al ratios of the gel had a crucial role in the formation of pure CHA, with a slight increase in Si/Al ratio (Si/Al=3.3), impurities of other phase (MER) were formed. Higher H<sub>2</sub>O/SiO<sub>2</sub> ratio affected the crystallinity of CHA zeolite, while lower H<sub>2</sub>O/SiO<sub>2</sub> ratio favored the formation of the MER phase. The aging time influenced both the particles' shape and size, and the rate of crystallization. At longer aging time, smaller CHA particles were synthesized with shorter crystallization time. The synthesized CHA zeolite in H-form (H-CHA) showed a high surface area and pore volume than the K-form (K-CHA). The reaction evaluation measurements of H-CHA showed that the Al-rich CHA zeolite was very selective to olefins. The deactivation rate and initial selectivity to olefins were linked to the reaction temperature. The selectivity of the Al-rich CHA zeolite in the MTO reaction was comparable to the commercial ZSM-5 and SSZ-13 catalysts. Ni, Mg, Fe, B and Zn were successfully incorporated to the CHA framework by an in-situ method. The incorporation of metals affected negatively the stability of the catalyst. However, the

metal incorporation had a significant enhancement to the total olefins selectivity at the beginning of the reaction.

For the second approach, up to our knowledge, for the first time, microwave irradiation has been utilized to synthesize an OSDA-Free Al rich CHA zeolite. Microwave heating decreased the crystallization time from 24 to 6 h. The synthesized CHA zeolites samples showed excellent activity in the MTO reaction. The selectivity to lower olefins was linked to the higher reaction temperatures and TOS. At higher temperature, 450 °C, the synthesized CHA zeolite was more selective to light olefins especially at the beginning of the reaction. Similarly, as TOS increased, the selectivity to light olefins was increased as well. This increase in selectivity with TOS was not significant at a reaction temperature of 450 °C. The highest boron incorporated CHA catalyst increased only the amount of olefins produced at the beginning of the reaction, while the low content boron incorporation did not contribute significantly to the activity of CHA catalyst.

## **5.1 Recommendations**

MOT reaction is one the most important reactions that significantly depends on the catalyst's acidity, morphology and topology. CHA zeolite is the most suitable topology for the MTO reaction, in which the small pore opening of the CHA cage strictly hinders the formation of aromatics. Regarding the acidity and morphology, the catalysts that we developed suffered from the fast deactivation due to the high alumina content which gives rise to higher acidity. Thus, to have a more efficient CHA catalyst, further modifications are highly recommended. We recommend post-modifications to the CHA catalyst to reduce the alumina content. The partial removal of aluminum can be achieved by applying acid and steam treatments. Moreover, impregnation of alkaline metals is

highly recommended for acidity reduction. Finally, we recommend fabricating CHA catalysts with small particles size by applying ball milling technique.

## Appendix

Symbol	Detail preparation method	Reference
<b>A</b>	The prepared aluminosilicate gel with the molar composition of 3.1-3.8Na <sub>2</sub> O:1.0Al <sub>2</sub> O <sub>3</sub> :10-35SiO <sub>2</sub> :200H <sub>2</sub> O:2.0-3.0Cu-TEPA was prepared by mixing 0.514g of sodium aluminate and 0.380 g of sodium hydroxide in required amount of demineralized water. Then, 1.149 g of copper sulfate pentahydrate (CuSO <sub>4</sub> .H <sub>2</sub> O) was added to the previous solution. Next, 1.07g of TEPA was added and stirred for 1 hr. Following this, 3.6 ml of a 31.6wt.% silica solution was added dropwise under vigorous stirring for 2 or 3 hours. Finally, the final gel was transferred to a Teflon and heated for 3 up to 6 days at 140 °C.	[45, 46]
<b>B</b>		
<b>C</b>	The CHA zeolite was prepared by the conversion of FAU zeolite with the presence of benzyl trimethyl ammonium hydroxide as SDA. The FAU zeolite was firstly prepared from NH <sub>4</sub> -Zeolite with Si/Al =2.8 and the then prepared FAU was dealuminated using steam and H <sub>2</sub> SO <sub>4</sub> . Seeds with Si/Al =16 have been used to assist the synthesis. In detail, educate amount of dealuminated FAU zeolite was added to a solution containing of the BTMAOH and sodium hydroxide or sodium chloride, optional. Finally, the final mixture was transferred to Teflon and hydrothermally treated at 125 °C for 7-21 days.	[48]
<b>D</b>	CHA zeolite was prepared from amorphous aluminosilicate gel using SSZ-13 seeds. The amorphous gel having a molar composition of 1 SiO <sub>2</sub> : 0.05 Al <sub>2</sub> O <sub>3</sub> : 0.40 Na <sub>2</sub> O: 0.09 K <sub>2</sub> O: 100 H <sub>2</sub> O prepared, firstly, by adding the aluminum isopropoxide to aqueous solution of sodium hydroxide and potassium hydroxide. After string for 1 h, fumed silica was added and stirred for have and hour. Following this, SSZ-13 seeds 20wt.% of the silica were added to the final solution and stirred for 10 minutes. Finally the gel was transferred to Teflon-lined stainless steel autoclave and hydrothermally heated with tumbling rate of 20 rpm for one day.	[44]
<b>E</b>	High silica CHA was synthesized using TEA as OSDA and FAU zeolite (CBV-720) as source of alumina and silica. The CHA formed at temperatures of 160 and 140 at various gel compositions. The effect of TEAOH, H <sub>2</sub> O and NaOH was studied. TEAOH/Si =0.4 and NaOH/Si =0.2 and at different water content (H <sub>2</sub> O/Si = 5,15 and 25) CHA was obtained. The PH of the synthesis gel was 12.7.	[49]

<b>F</b>	CHA zeolite was prepared by the conversion of FAU zeolite, HY zeolite (Si/Al = 2.8, TOSOH). The synthesis of CHA zeolite was achieved by mixing the HY-zeolite to an aqueous solution of potassium hydroxide with a final gel molar composition of 5.5 SiO <sub>2</sub> –1.0 Al <sub>2</sub> O <sub>3</sub> –4.0 KOH–224 H <sub>2</sub> O. The final mixture was stirred for 2 hours and then transferred to a polypropylene bottle, and heated at 100 °C for 5 days.	[50]
<b>G</b>	Chabazite SSZ-13 with a gel composition of 10 TMAOH: 10 Na <sub>2</sub> O:3 Al <sub>2</sub> O <sub>3</sub> : 100 SiO <sub>2</sub> : 4400 H <sub>2</sub> O was synthesized by first mixing 2 g of 1M of sodium hydroxide, 2g of deionized water and 4g of 0.5M of TMAOH. Then, 0.05g of aluminum hydroxide was added to the later solution and stirred vigorously for 30 minutes. After that, a 0.6g of fumed silica was added and the solution stirred at room temperature till it homogenized. Finally, the final gel was transferred to Teflon-lined stainless autoclave and heated at 160 °C for 4 days.	[51]
<b>H</b>	SSZ-13 was prepared by first mixing a solution composing of 0.45 g Na <sub>2</sub> O, 1.46 g SiO <sub>2</sub> , 3.10 g H <sub>2</sub> O with 6 ml of water and 1.56 g of the TMADAI ion. Then, another solution composing of 6 ml H <sub>2</sub> O 0.24 g of Al <sub>2</sub> (SO <sub>4</sub> ) <sub>3</sub> .16H <sub>2</sub> O and 0.67 g NaOH added to the first solution and stirred till homogeneous gel was obtained. After that, the final gel was transferred to a stainless steel pressure reactor and crystallized for 6 days at 140 °C.	[52]
<b>I</b>	Materials:Ammonium fluoride, sodium fluoride and potassium fluoride (sigma Aldrich) Molar composition: 1SiO <sub>2</sub> :xAl <sub>2</sub> O <sub>3</sub> : 0.39K <sub>2</sub> O:yNH <sub>4</sub> F:35H <sub>2</sub> O,x=0.05-0.33, y=0.1-0.5. Typical synthesis: an amount of aluminum hydroxide was added to an alkaline solution containing (7.0 g potassium hydroxide +67.6g of demineralized water) under heating at 80 °C. Then cold to room temperature. After that, an amount of ammonium fluoride and Ludox TM-40 colloidal silica (Sigma–Aldrich, 40 wt.% SiO <sub>2</sub> water suspension) were added in the clear alkaline aluminate solution. This mixture stirred at room temperature for 6h and then transferred to Teflon and hydrothermally treated at 160 °C for several time.	[44]
<b>J</b>	20g of Hi-Sil 233 (source of silicon oxide) placed in a vessel. Reheis F-2000 alumina (1.7 grams) was dissolved in 5 grams of a 50% aqueous NaOH solution and then added to the Hi-Sil 233 in the vessel. The resulting mixture is mixed thoroughly. To the resulting mixture was added 1 gram of SSZ-13 seed crystals, and the mixture thoroughly mixed again for 5 minutes. 23.3 Grams of a 2.36 mmole/gram solution of benzyl trimethylammonium hydroxide was added slowly to the mixture while mixing. 8 Grams of D.I. water was added slowly and the resulting mixture mixed thoroughly for 1 hour. The resulting mixture was in the form of slightly wet granules with a volatiles content of 59.6%.

## Vitae

Name : Galal Atef Ahmed Nasser

Nationality : Yemen

Date of Birth : 11/29/1988

Email : galal5522@gmail.com

Address : 90th Street, Al-mansorah, Aden, Yemen

Academic Background : B.Sc. Chemical Engineering, (2009-2015),  
KFUPM, Dhahran, Saudi Arabia.  
M.S Chemical Engineering, (2015 - 2017),  
KFUPM, Dhahran, Saudi Arabia.

Research Background :

- Development and characterization of **Nano-particles zeolites for Petrochemical and Refinery industries.**
- Fabrication of **Novel and Cost-Effective catalysts** for the conversion of **methanol to olefins**;  
The project is supported by **SABIC** through **CENT, KFUPM.**
- Modification and Characterization of Natural zeolites for n-hexane cracking to olefins and the conversion of DME to olefins.
- Designed an **Air-left Bioreactor** used for carbon dioxide capture by utilizing micro-green algae. The project was part of the undergraduate research supported by KFUPM.

Research Outcome :

▪ **Published papers**

1. **Galal Nasser**, Teguh Kurniawan , Koji Miyake , Ahmad Galadima , Yuichiro Hirota ,Norikazu Nishiyama , Oki Muraz. *Dimethyl ether to olefins over dealuminated mordenite (MOR) zeolites derived from natural minerals*. Journal of Natural Gas Science and Engineering, 2016. **28**(Supplement C): p. 566-571.
2. **Galal A. Nasser**, Teguh Kurniawan, Teruoki Tago, IdrisA.Bakare, TaichiTaniguchi, YutaNakasaka, Takao Masudac,Oki Muraza. *Cracking of n-hexane over hierarchical MOR zeolites derived from natural minerals*. Journal of the Taiwan Institute of Chemical Engineers, 2016. **61**(Supplement C): p. 20-25.
3. Idris A. Bakare, Oki Muraza, Taichi Taniguchi, Teruoki Tago, **Galal Nasser**, Zain H. Yamani, Takao Masuda. *Steam-assisted catalytic cracking of n-hexane over La-Modified MTT zeolite for selective propylene production*. Journal of Analytical and Applied Pyrolysis, 2015. **116**(Supplement C): p. 272-280.

▪ **Submitted Publications:**

1. **Galal A. Nasser**, Oki Muraza, Toshiki Nishitoba, Zuhair Malibari, Toshiyuki Yokoi. *Microwave-Assisted Hydrothermal Synthesis of Al-rich CHA Zeolite from Amorphous Aluminosilicate Gel in Presence of Seed*. Submitted to: **Crystal Growth & Design** Journal.

▪ **Work which are in progress:**

1. **Galal A. Nasser**, Oki Muraza, Toshiki Nishitoba, Zuhair Malibari, Toshiyuki Yokoi. *OSDA-free chabazite (CHA) zeolite synthesized from amorphous aluminosilicate gel in the presence of fluoride for selective methanol-to-olefins*. Will be submitted soon to: **Mesoporous Microporous Materials** Journal .
2. **Galal A. Nasser**, Oki Muraza, Toshiki Nishitoba, Zuhair Malibari, Toshiyuki Yokoi. *In-situ incorporation of transition and alkaline earth metals in the framework of OSDA-Free CHA zeolites for selective methanol-to-olefins*. In progress.

▪ **Submitted Publications:**

One patent from the MS thesis work is ongoing.
